The Australian Centre for International Agricultural Research (ACIAR) was established in June 1982 by an Act of the Australian Parliament. Its mandate is to help identify agricultural problems in developing countries and to commission collaborative research between Australian and developing country researchers in fields where Australia has special research competence.

Where trade names are used this constitutes neither endorsement of, nor discrimination against, any product by the Centre.

ACIAR PROCEEDINGS

This series of publications includes the full proceedings of research workshops or symposia organised or supported by ACIAR. Numbers in this series are distributed internationally to selected individuals and scientific institutions. Recent numbers in the series are listed inside the back cover.

Hartman, G.L., and Hayward, A.C., ed., 1993. Bacterial wilt. Proceedings of an international conference held at Kaohsiung, Taiwan, 28–31 October 1992. ACIAR Proceedings No. 45, 381 p.

Asian Vegetable Research and Development Center (AVRDC)
Australian Centre for International Agricultural Research (ACIAR)
International Crops Research Institute for the Semi-Arid Tropics (ICRISAT)
International Potato Center (CIP)
Rothamsted Experimental Station

Contents

Preface

THE first international conference on bacterial wilt was held in Raleigh, North Carolina, USA, in July 1976. Since then there have been several other meetings which were either regionally based, like the one held at PCARRD, Los Baños, the Philippines in October 1985 (ACIAR Proceedings 13, 1986) or devoted to particular crops such as peanut (ACIAR Proceedings 31, 1990) or potato (International Potato Center-CIP 1988. Bacterial diseases of the potato. Report of the planning conference on bacterial diseases of the potato, 1987). The second truly international meeting on bacterial wilt of all crops was held in Kaohsiung, Taiwan, from 28–30 October 1992.

There are several compelling reasons why the subject of bacterial wilt should be addressed at international meetings dedicated to the topic. The disease is primarily of importance in the tropics and subtropics, that is, of the developing rather than the developed world, and the literature on the subject is widely scattered and of uncertain status, partly reflecting the wide range of hosts and localities where the disease is endemic, and the lack of coordination of effort. The amount of research effort directed at bacterial wilt in North America and Europe is necessarily somewhat limited, and tends to fluctuate and lack continuity. Plant pathologists and plant breeders working in the tropics recognise the slow progress in reducing the serious depredations caused by bacterial wilt on a range of major food crops and are frustrated in their attempts to control the disease by lack of knowledge about the basic biology of the pathogen. One consequence of predicted global warming is that significantly different climatic regions, some them more favourable to bacterial wilt, will be created from those to which major crop and pasture plants are currently adapted. The expected impact of these changes gives urgency to greater research effort on bacterial wilt. All of these are reasons why interested workers should come together to discuss advances, establish priorities for future research, and maintain formal and informal networks, in the general interest of a more coordinated research effort and a more efficient use of resources. It is greatly to be hoped that these proceedings will not only encourage this processs but also the holding of future international meetings at more regular intervals of, say, five years.

Phenotype, Genotype and Phylogeny: Identification and Diagnostic Methods

Bacterial Wilt: Past, Present, and Future

L. Sequeira*

It is certainly a pleasure and an honour to have an opportunity to open this International Symposium on Bacterial Wilt. I am grateful to the Organising Committee, and to Drs Hartman and Hayward, in particular, for the invitation to speak about my favourite subject: bacterial wilt. Having spent almost 40 years of my professional life in a sometimes futile attempt to unlock some of the secrets of *Pseudomonas solanacearum*, there is an almost irresistible urge to recount some of the pleasures as well as some of the frustrations of life with this organism. My purpose today, therefore, is to provide you with a bit of philosophy about our field: where we have been, where we are now, and what we may look forward to in the future.

I trust that you will not mind if I personalise much of this account. I could have given you yet another listing of the accomplishments that a long and distinguished group of investigators has made since I came into the field of bacterial wilt. We have been blessed, however, by a long series of excellent reviews in recent years, including those of Ivan Buddenhagen (1986), Chris Hayward (1991), Chris Boucher et al. (1992), and Tim Denny et al. (1991) that give an excellent account of the literature on the biology, epidemiology, host–parasite interactions, and genetics of *P. solanacearum*. It would not serve any useful purpose to re-review this information. It would be impossible to evaluate the whole field in a short talk, in any case. Thus, the purpose of this talk is to present a highly personalised account of four aspects of bacterial wilt that I have selected because they have been the focus of my research interests for so many years: the evolution, survival, dissemination, and host–parasite interactions of *P. solanacearum*. I will attempt to use the ultimate reductionist approach, i.e. a) what does the information encoded in its DNA tell us about the evolutionary past of *P. solanacearum*, b) what genes are important in its present interactions with the soil and with the plant host, and c) to what extent can we predict new genomic rearrangements that may increase its host range and perhaps cause havoc in new and unsuspected hosts? But first, a bit of personal history.

*Department of Plant Pathology, University of Wisconsin, Madison, Wisconsin, 53706, USA

Brief Encounters of the Third World

For me, life with *P. solanacearum* has been, like most marriages, interesting but characterised by periods of complete elation as well as by periods of utter frustration. Interest and frustration have a common origin; *P. solanacearum* chooses to do things differently from other bacterial pathogens. Thus, it is frequently dangerous to apply to *P. solanacearum* many of the findings from other bacterial-plant associations. It is a difficult and treacherous organism, astonishing in its unpredictability. I am no longer surprised by what this bacterium is able to do or by the fact that it sometimes reveals its secrets to us but that, for the most part, it remains aloof, secretive, and impervious to any attempts at investigation. Yes, we do know a great deal more about bacterial wilt today than we did when Arthur Kelman (1953) published the first compre-

hensive review in. No, we have not answered many of the key questions regarding the basic biology of the organism. In this regard, it is instructive that Ivan Buddenhagen (1986) chose to close his excellent review at the last regional meeting on bacterial wilt in 1985 in Los Baños by merely quoting the same series of unanswered questions that he and Arthur Kelman had listed in their review of 1964 (Buddenhagen and Kelman 1964).

Slow progress is, of course, due not solely to the inherent difficulties of the system, but to the relatively low number of investigators that have chosen to pursue basic research with *P. solanacearum*. Yet, there has been a quantum leap in the number of laboratories dealing with this bacterium today as compared with 1951, the first time I encountered my future scientific consort and nemesis. As a fledgling graduate student at Harvard, I was pursuing field data for my Ph.D. thesis at IICA in Turrialba, Costa Rica on a totally unrelated problem on coffee. There, I met Eddie Echandi who was doing research on bacterial wilt of potatoes and was suffering from a common malady that afflicts most researchers who deal with *P. solanacearum*: his cultures would lose virulence very rapidly. I attempted to assist Eddie, but to little avail. We were a few years too early in this work, for it was not until 1954 that Arthur Kelman established the means to retain virulence in cultures of this organism, which he described in his now classic paper on the relationship of colony appearance to virulence (Kelman 1954). It is sobering to realise, however, that after 40 years we still do not know the nature of the mechanisms involved in spontaneous loss of virulence.

My next encounter with *P. solanacearum* proved to be more permanent. In the summer of 1953, having just returned to Costa Rica from a year's postdoctoral work in Brazil, I found myself unemployed and thoroughly demoralised until, several months later, I met Harry Stover. Harry was head plant pathologist for United Fruit Company in La Lima, Honduras, and he was searching for someone who could look at the microbiological changes associated with flood fallowing, then the only means to control *Fusarium* wilt of bananas. I accepted the position. Harry inquired whether, while I waited for the visa that would allow me to work in Honduras, I would be willing to visit the plantations at Coto Sur, the newest division of United Fruit in Costa Rica and where, reportedly, a wilt disease unlike *Fusarium* wilt was causing serious problems. I agreed, but did not realise then that this was the beginning of a new encounter with *P. solanacearum* and of an 8-year sojourn in what was then a jungle outpost in one of the most remote and inaccessible corners on the southwest coast of Costa Rica.

At the time, the Coto Valley was being planted to bananas, which required draining a large flood plain and felling thousands of acres of rain forest. Bananas were planted in the midst of this rotting morass of foliage, trunks, roots, and stumps, but as the plants reached maturity, a premature fruit rot appeared which was often preceded by wilting of the youngest leaves. It did not take me long to establish that this new disease was Moko disease, which is caused by *P. solanacearum* and had been described previously from the Guyanas and Trinidad. That determination sealed my fate, for it was soon thereafter that company officials decided to establish a laboratory at Coto which would serve as a centre for research on Moko disease.

I have retold this story of my initiation into bacterial wilt research (Sequeira 1988) only to make an important point: the initial evidence supported the concept that *P. solanacearum* strains, capable of attacking bananas, were present in virgin woodland and presumably had evolved on native species. It did not take long for Ivan Buddenhagen and myself to establish that the pathogen was endemic in several species of the native musaceous genus *Heliconia*, a common component of the forest understory (Buddenhagen and Kelman 1964; Sequeira and Averre 1961). The important conclusion, however, was that only relatively few strains could cause Moko disease of bananas; most of the strains from *Heliconia* were pathogenic only on *Heliconia*. Planting several thousand acres of bananas, *Musa* hybrids which are not native to the American tropics, provided an effective screen. Only those strains capable of attacking bananas became the predominant feature of the soil environment, while the vast majority of the *Heliconia* strains declined as their hosts disappeared. This was an unusual opportunity to observe evolution in action. A wonderful example of the pernicious influence of humans who, by disturbing the natural balance in the forest, caused epidemics of vast proportions the effects of which are being felt even today.

Months of tortuous treks through the jungle provided ample evidence that the native *Heliconia* population carried a wide variety of strains of the bacterium, but they were present in discrete pockets throughout the Coto landscape (Sequeira and Averre 1961). Surprisingly, try as we might, we were never able to isolate Moko disease-causing strains from *Heliconia*, although the scattered, wilting banana plants provided ample evidence of their existence. One could increase the virulence of a particular *Heliconia* strain to bananas by serial passage, but only within certain limits that did not include the full symptoms of Moko disease. Evidently, the Moko-causing strains were rare in the rain forest but became a serious problem on bananas only because they could be readily

transmitted from plant to plant by mechanical means during the pruning and harvesting operations (Sequeira 1958). How these same strains are transmitted among the heliconias in the natural forest is, of course, unknown.

These exciting and interesting findings about the distribution of such a distinct group of strains of *P. solanacearum* in the wild stimulated a number of important questions regarding the evolution of the pathogen. Did it evolve in the Coto Valley from some primeval soil bacterium? Or, did *P. solanacearum* vary so quickly that the *Heliconia* strains could adapt readily to a new host, bananas? If so, why only the *Heliconia* strains? Other strains that attacked solanaceous hosts coexisted with the *Heliconia* strains in the soils of the Coto Valley, yet none of the former attacked the triploid cultivars of banana. I preferred to think that *P. solanacearum* originated only once, early in evolutionary history and that, from that centre of origin, it spread throughout the warmer regions of the world. I favoured the notion that geographical isolation played an important role in the coevolution of the bacterium with specific hosts, such as heliconias in the Caribbean region. These thoughts remained with me for more than 30 years until the new techniques of molecular genetics allowed my colleagues, Douglas Cook and Elizabeth Barlow, to begin an analysis of the evolutionary history of *P. solanacearum*.

A Peek into the Life and Times of *P. solanacearum*

There is increasing evidence that *P. solanacearum* is an ancient species that is only remotely related to other species of *Pseudomonas*. The fact that, taxonomically, *P. solanacearum* as a group stands pretty much by itself within the pseudomonads has been known for many years. Whether one uses numerical analysis of phenotypic traits (Colwell and Liston 1961), DNA–DNA or RNA–DNA hybridisation (De Vos et al. 1985; Palleroni et al. 1973), the conclusion is the same: *P. solana-cearum* strains form a distinct group that bears little relationship to other plant-pathogenic pseudomonads and, indeed, to the xanthomonads. That conclusion has now been confirmed on the basis of sequence analysis of the 16S fragment of ribosomal RNA (Stackebrandt et al. 1988). It seems likely that *P. solanacearum* is a member of the beta subdivision of the Proteobacteria, where it finds itself in rather odd company. This is the group that contains the purple photosynthetic bacteria and their non-photosynthetic relatives. The closest relative to *P. solanacearum* is *P. cepacia*, which is in a phylogenetic branch that contains a preponderance of non-photosynthetic species, represented by genera such as *Spirillum*, *Alcaligenes*, *Aquaspirillum*, etc.(Stackebrandt et al. 1988). *P. solanacearum* shares with other non-pigmented pseudomonads in this group (*P. caryophylli*, *P. cepacia*, and *P. marginata*) certain metabolic properties, including the ability to produce 2-hydroxyputrescine in culture (Busse and Auling 1988). The 16S RNA sequence data confirmed the phylogenetic relationships that DeVos et al. (1985) had established back in 1983 on the basis of DNA-rRNA hybridisation. The general conclusion is that *P. solanacearum* as a group is highly homogeneous, phylogenetically distinct, and only distantly related to other homology groups within the genus *Pseudomonas*.

If one accepts at face value the universal phylogenetic tree constructed by Woese (1987) from rRNA sequence comparisons, it is clear that all of the bacteria in the group of Eubacteria that includes *P. solanacearum* are relatively ancient species that share some unique metabolic properties derived from an ancestor that may have been a purple, photosynthetic bacterium. I bring out these points only to emphasise the fact that *P. solanacearum* occupies a rather unique place in bacterial evolutionary history and that we should not be surprised, therefore, by the fact that it exhibits some rather unusual genetic characteristics. For example, in addition to its peculiar ribosomal RNA structure (Stackebrandt et al. 1988), one can point to the preponderance of unusual transcriptional start codons in its DNA (Huang and Schell 1990a) and the two-step process, involving a lipoprotein intermediate, that it employs to export extracellular enzymes such as endoglucanase (Huang and Schell 1990b).

It is interesting that within the rRNA homology group II, *P. solanacearum* bears little relationship to the other plant pathogens within this group. The closest are *P. pickettii* and *P. syzygii*, the first an occasional pathogen of humans (Ralston et al. 1973) and the second, the agent of a wilt disease of clove in Sumatra (Roberts et al. 1990).

Its worldwide distribution, its association with native plants growing in virgin soils, and the large number of strains that exist in distinct geographical regions, provide ample evidence that *P. solanacearum* has been present in tropical soils for eons. As Buddenhagen and Kelman (1964) have suggested, it is possible that early in geological history *P. solanacearum* was a pathogen of the ancestors of modern plants. Modern methods of genetic analysis have made it possible to obtain a picture of the possible evolution of *P. solanacearum*; the results support the notion that it originated from a common ancestor, possibly at a single location.

The use of restriction fragment polymorphism (RFLP) analysis, which involved southern hybridisation of DNAs of over 200 strains of *P. solanacearum*

with seven different probes encoding information essential for virulence and induction of the hypersensitive response (HR), has provided evidence for the existence of about 35 groups that share common DNA fragments (Cook et al. 1989). The 200 strains involved in this study comprised all known races (Buddenhagen and Kelman 1964) and biovars (Hayward 1964). Similarity coefficients among RFLP groups were determined and then used for cluster analysis, which could then be depicted in the form of a dendrogram. It was immediately apparent that all strains could be divided into two main groups that had only 13.5% similarity between them (Cook et al. 1989). Division I contains all members of race 1, biovars 3, 4, and 5; Division II contains all members of race 1, biovar 1, and races 2 and 3. Within each division, the coefficients of similarity are very high: 78% for Division I and 62% for Division II.

The major divisions also corresponded, with a few exceptions, to the geographic distribution of the strains: 90% of the strains in Division I were from Asia and Australia, whereas 98% of those in Division II were from the Americas. The inevitable conclusion is that, early in evolution, *P. solanacearum* became divided into two groups which then evolved in geographic isolation giving rise to strains that are typical of the Old World and of the New World. We excluded from this analysis all strains of race 3 from potato that had been collected in Africa, Asia and Australia, because it was evident from the RFLP patterns that all belonged to the same RFLP groups, 26 and 27, which originated from the Andean regions in South America. Since, statistically, there is no possibility that these same patterns could have evolved independently, we concluded that humans had been responsible for disseminating race 3 on infected potato tubers from their centre of origin in Latin America to the rest of the world (Cook et al. 1991).

The RFLP data provide several additional examples of the role of geographic isolation in the evolution of *P. solanacearum*. Strains from ginger and mulberry, for example, form distinct groups that are restricted to certain parts of Asia. The strains from *Heliconia* are in groups that are restricted to the American tropics and, within these, those that cause Moko disease of bananas are not distinguishable except for the insect-transmitted strains associated with relatively recent epidemics on bananas and plantains. Each of these epidemics in Central and South America appears to be associated with a specific RFLP group of strains (groups 24, 25, and 28).

In contrast with the case of race 3, which consists of a very compact group of strains originating in the Andean region, there is evidence that strains capable of attacking bananas evolved independently in the Asian and American continents. An old disease of bananas, called blood disease, has now been shown to be caused by *P. solanacearum* (Eden-Green and Sastraatmadja 1990). The RFLP data confirm this diagnosis; all isolates that we examined contained DNAs that hybridised with our seven probes. The RFLP patterns we obtained, however, are so different from all other strains that it is evident that this group bears little relationship to the American race 2 strains. It is likely that these strains occupy a separate branch within the Division I strains and represent a clear case of convergent evolution.

The RFLP analysis has also helped us to resolve several taxonomic problems that would have been difficult to approach by other means. For example, it is well known that there is correspondence between race 3 and biovar 2 (Buddenhagen and Kelman 1964). Yet, not all biovar 2 strains belong in race 3. This was not immediately evident following the isolation by Martin and collaborators in Peru (Martin et al. 1981) of biovar 2 strains from the Amazon Basin capable of attacking potatoes. The RFLP data show quite clearly that they belong to groups that are distinguishable from the highland biovar 2 strains (Cook et al. 1991). Is it only a coincidence that these strains share certain biochemical features? Are the lowland strains the progenitors of strains that acquired the capacity to attack potatoes at high elevations and to multiply and survive at relatively low temperatures? We can only speculate as to the answers to these questions.

The general conclusion from the RFLP analysis is that *P. solanacearum* is an ancient but rather homogeneous taxon. This long evolution, in combination with geographic isolation, has resulted in a large number of rather divergent strains, but the species does not appear to be as highly variable as once thought. The presence of clonal populations within very extensive geographical areas (e.g. the SFR strains that attack bananas in Latin America) indicates a great deal of stability in the species. This is an inevitable conclusion in spite of the continued appearance of strains that have an expanded host range (e.g. the relatively recent reports of new strains capable of attacking *Eucalyptus* in Brazil or *Casuarina* in China).

A Soil-Borne Pathogen that is Poorly Adapted for Survival in the Soil

A persistent problem in attempts to control bacterial wilt by crop rotation has been the unpredictability of the survival of *P. solanacearum* in the soil. The early experience of Dutch researchers in Indonesia pointed to the need for long periods (up to 8 years) of rotation with non-susceptible crops that had to be employed to allow planting of tobacco in certain soils, and then only for a

single season (Kelman 1953). The extensive experiments of Smith (1944) in North Carolina led to the notion that *P. solanacearum* could persist for several years in fallowed soil, even in the absence of vegetation. In contrast, race 2 disappeared rapidly from soils in Costa Rica once weed hosts were eliminated, thus allowing replanting with bananas after six months (Sequeira 1962). Almost every attempt to measure survival in the laboratory has led to the conclusion that populations drop below the detection level within a few months, even under optimum moisture and temperature conditions (Graham et al. 1979).

These incongruities may be related to: a) inherent differences in ability of different strains to survive in the soil; b) differences in the composition of competing microfloras; and c) differences in the methods used for assaying the bacterium. I hold the rather iconoclastic view that *P. solanacearum* does not survive in the soil for prolonged periods because it is not a strong competitor. We all know that this organism is difficult to isolate from rotting tissues; it lives in the highly protective environment of the xylem vessels, but confronted with competition in the outside, it does poorly. Therefore, how does the bacterium survive in the soil for prolonged periods? The answer may be found in the report of Granada and Sequeira (1983) on survival of this organism in soils and on or in plant roots. This paper has not received wide recognition, perhaps because it was based on greenhouse and growth room experiments. Nevertheless, we concluded that *P. solanacearum* does not survive in the soil itself but on or in plant roots. The bacterium appears to survive by continually infecting the roots of susceptible or carrier plants or by colonising the rhizospheres of non-host plants.

Survival of *P. solanacearum* in the rhizosphere has been documented, mainly as a result of the work of Quimio and Chan (1979) who reported gradual declines of the populations of the bacterium in the rhizospheres of rice and maize, and increases in the rhizosphere of *Portulaca oleracea*. Perhaps even more significant was the finding by Granada and Sequeira (1983) that the bacterium invades the roots of presumed non-hosts, such as bean and maize. Long-term survival was associated with localised or systemic infection of plants that did not express symptoms of bacterial wilt. The existence of such symptomless carriers has been well documented in the literature. For example, in India, *Ageratum conyzoides* and *Ranunculus scleratus* showed no symptoms even though the bacterium was readily isolated from surface-sterilised roots (Sunaina et al. 1989). Thus, it is evident that several important crop plants may act as carriers of the bacterium. This may explain the failure of crop rotations. For example, in Costa Rica, Jackson and Gonzalez (1981) reported that rotations with maize, cowpea, sweet potato, or wilt-resistant tomatoes, failed to reduce the incidence of disease on potatoes planted one year later.

The most logical explanation for long-term survival of *P. solanacearum* is its association with plant roots. This is merely a hypothesis, which must be tested in the field. Survival is an issue that is fundamental to our understanding of the biology of *P. solanacearum* as well as to the design of rational means of control. It is evident, for example, that rotations with presumed non-hosts often fail because the crop acts as a carrier and can, in fact, lead to multiplication of the bacterium and maintenance of a high inoculum in the soil. In general, however, few plants of non-host crops, such as maize, become infected; thus, infection remains localised, leading to slow decreases in bacterial populations with time.

A related problem concerns the possibility that *P. solanacearum* may exist as a leaf epiphyte under some conditions. Although there is limited evidence, it seems likely that, under conditions of high relative humidity, epiphytic colonisation of *Capsicum* can occur and, in fact, can lead to lesion development on the leaves. Survival was detected for more than 15 days when the pathogen was sprayed on the upper surface of *Capsicum* leaves and the plants were maintained at 95% relative humidity (Moffett et al. 1981). As Hayward (1991) has pointed out, the epiphytic phase in the life cycle of the bacterium may be an important source of inoculum for the renewal of soil populations. Future investigations should focus on field studies designed to determine whether or not epiphytic growth plays a significant role in the epidemiology of the bacterial wilt organism.

The Process of Infection: a Continuing Enigma

It is surprising, indeed, that at this late date we should know so very little about the processes of penetration of roots, establishment, and colonisation of the vascular elements of a susceptible host by *P. solanacearum*. It is even more surprising that so very little effort has been made to unravel this important part of the life cycle of the bacterium since Arthur Kelman and I reported on our attempts to determine how infection occurred in tomatoes (Kelman and Sequeira 1965). At that time, we concluded that, for plants grown in sand and subjected to subirrigation with nutrient solution, a population of at least 50000 bacteria per mL was necessary for infection to occur in the absence of wounding. When the roots were wounded, only a few bacteria per mL were needed to cause infection, a fact that is consistent with the frequent observation that mechanical damage to roots in the field, whether by

cultivation practices or by nematode infection, results in rapid increases in the incidence and severity of bacterial wilt. A more important observation, made by placing inoculum on agar along the length of the roots, was the fact that penetration occurred along the points of emergence of secondary roots. Later in the disease cycle, bacteria are extruded in exceedingly high numbers from the same location on the roots.

These data are consistent with the frequent observation of successive involvement of plants along the row in the field. As the population of the bacterium in the soil increases, the possibility of infection of healthy roots via the lateral root emergence points increases. We concluded at the time that 'the concept that individual plants are each infected separately from a residual population of the wilt bacterium in the soil must be modified'. It is surprising that no one, to my knowledge, has challenged that statement.

Conclusive proof that the bacteria enter and egress directly from the points of secondary root emergence still awaits confirmation by careful histologic studies. It is ludicrous that at this stage of high tech science we still do not know for certain how *P. solanacearum* infects the host via the roots, and indeed, whether it infects different hosts in the same manner.

It is interesting to consider the possible reasons for the very high cell number of bacteria that are required for penetration of unwounded roots. One possibility is that the bacteria must digest their way through the mucilaginous coating at the edge of the emerging root. Penetration at these points may require the massing of cells in order to digest enzymatically this mucilaginous sheath. These mucilages are pectinaceous in nature and, therefore, it is not surprising that endo- and exo-pectinases should be important factors in virulence of *P. solanacearum*. The importance of these enzymes in penetration of the host is rarely tested, however, for most of the virulence assays are based on stem inoculation, which bypasses the root infection process. It is also evident that pectinases must be important at other points in the life cycle of the bacterium, as I shall point out later.

We are fortunate in that we know a considerable amount about the genes that control pectinase synthesis and that we are beginning to understand their regulation. At the University of Georgia, Mark Schell, Tim Denny and collaborators have cloned and characterised the gene *pehA* that is involved in the synthesis of the polygalacturonase produced in ordinary culture media (Schell et al. 1988). In our laboratories, Caitilyn Allen has shown that total PG activity per cell increases in the presence of the plant (Allen et al. 1991, 1992) but that this induction involves mostly two additional PGs, *PehB* and *PehC*. We will learn a great deal more about these genes and their regulation at this conference. Suffice it to say that pectin oligomers are good inducers of PG and we can assume that they are present at the point of emergence of secondary roots, where microbial degradation of mucilage must occur very rapidly. Thus, we can envision that the ability to produce increasing amounts of pectinase and the ability to utilise the products of mucilage breakdown may lead to an environment that is conducive to rapid multiplication and, thus, to rapid colonisation of the space between the emerging root epidermis and the root cortex.

How does the bacterium reach the vascular system? Unfortunately, there is no cytological evidence of this critical stage in penetration, but it is assumed that the bacterium has to digest its way through the primary wall of the weakened cortical cells as well as of the tracheary elements, where it is exposed between the spiral thickenings. This is probably the reason why mutants that lack endoglucanase (cellulase), obtained by site-specific mutagenesis of the *egl* gene, are substantially reduced in virulence to tomato seedlings (Schell et al. 1988). Furthermore, a double mutant for endoglucanase and PG was shown to be less virulent than an endoglucanase single mutant (Denny et al. 1990). Although *P. solanacearum* is not a tissue-macerating bacterium, it must degrade plant cell walls at various stages in its life cycle, one being the penetration of the vascular connections of secondary roots. Since the primary cell wall is composed mostly of pectin, cellulose, and hemicelluloses, it is not surprising that the ability to degrade these compounds should be intimately tied to the virulence of the bacterium.

Life in a Black Hole

Several years ago, George Pegg referred to the multiplication of vascular invaders of plants as 'life in a black hole'. This is an appropriate term for the location where *P. solanacearum* has chosen to complete its life cycle, a habit that leads to so much grief for the plant host as well as for the growers. The xylem vessel is a rather foreboding environment that has only one advantage for the bacterium: an isolated location where it can avoid competition, multiply freely, and roam at will with the aid of the transpiration stream.

The bacterium, however, must overcome at least three problems: a) it must not cause a hypersensitive response (HR) that would lead to rapid death of the parenchyma cells that surround the primary xylem; b) it must prevent attachment to cell walls, particularly when multiplying in intercellular spaces, i.e. during the process of penetration; and c) it must obtain sufficient nutrients in the lumen of the xylem, an environment that contains only water and traces of sugars and amino acids, encased by an impervious substance, lignin.

There is little question that *P. solanacearum,* over a period of long evolution with the host, has developed highly coordinated systems to resolve these problems. We know some of the details, as I will indicate, but this is precisely the area that holds the most promise for future investigation.

First, the matter of HR induction. We now know that this process is mediated by sets of *hrp* genes that control both HR induction in incompatible hosts and pathogenicity in compatible hosts. There are at least two sets of *hrp* genes and we know a good deal about the genetic organisation of one cluster as a result of the extensive work in Chris Boucher's laboratory (Arlat et al. 1992; Boucher et al. 1992). The recent discovery that this *hrp* cluster codes for proteins that are important in export of extracellular proteins in many different Gram-negative bacteria is a key finding that will allow a detailed examination of the regulation of pathogenicity. Another important finding from Steve Beer's laboratory is that *P. solanacearum* strain K60 contains a homologue of the gene that codes for harpin, a peptide responsible for induction of the HR and first isolated from *Erwinia amylovora* (Beer et al. 1992). Thus, harpin may be the elusive HR inducer that so many of us have searched for in the past. I believe that Beer's as well as Boucher's laboratories have confirmed the production of a harpin-like HR inducer from strains K60 and GM1001, respectively.

To place this information in the proper context, it is important to remember that all of the HR work has been done by infiltrating the intercellular spaces of tobacco leaves, a rather unnatural environment for *P. solanacearum*. We must demonstrate that the HR is induced at the point of penetration of the cortical tissue in the roots—that is where the action is. In addition, we know that harpin production is induced in minimal medium. But is it also induced in the plant? Work with other bacterial-plants systems would suggest that *hrp* genes are induced *in planta*, but, if so, why is the HR repressed in the compatible combination? These are all fundamental questions that are now amenable to investigation by modern methods.

Assuming that the bacterium is able to inhibit or delay a host response, it must now face the problem of attachment to plant cell walls. Back in 1976, we reported that strains that lack extracellular polysaccharide (EPS) are rapidly attached and enveloped at the surface of mesophyll cells in tobacco leaves (Sequeira et al. 1977). The importance of that observation was not readily apparent until we determined that attachment to cell walls of suspension cultured tobacco cells is mediated by the interaction of the acidic lipopolysaccharide (LPS) of the bacterium and a lectin-like, highly basic hydroxyproline-rich glycoprotein that is present at the surface of the host cell (Duvick and Sequeira 1984a,b). Significantly, that interaction is efficiently inhibited by bacterial EPS. Thus, EPS appears to provide an effective coating for potential binding sites that, if exposed, would immobilise the bacteria at the plant cell. This seems to be one reason why mutants, spontaneous or induced, that lack EPS are affected in virulence, although to a different degree depending on the site of the mutation (Kao and Sequeira 1992). EPS, of course, is also important in vascular plugging and wilt induction.

The importance of EPS as a virulence factor, first stated by Kelman (1954), justified the increasing efforts at various laboratories, including our own, to determine the structure of the main components of EPS (Orgambide et al. 1991) and to clone the genes involved in its biosynthesis (Cook and Sequeira 1991; Kao and Sequeira 1992) as well as in the regulation of its production (Denny et al. 1991). The structure of a component of the acidic fraction of EPS has been elucidated and found to be a repeating unit of two unusual amino sugars, bacillosamine (2, 4-diamino-2, 4, 6 trideoxy-glucose) and galactosaminuronic acid (Orgambide et al. 1991). Some of the biosynthetic genes are located in one cluster called OPS, which we have determined to contain at least seven complementation units whose function affects both EPS and LPS synthesis. One *ops* complementation unit, *opsG*, is involved in the synthesis or assembly of the rhamnose residue in LPS and EPS (Kao and Sequeira 1991, 1992). We predict that *opsC* and *opsD* are involved in the synthesis of N-acetyl glucosamine and xylose, but this remains to be determined.

Another important cluster of EPS genes in *P. solanacearum* is the EPSI and EPSII group of genes which map to adjacent locations in the bacterial chromosome and in a position distinct from that of the *ops* cluster (Denny et al. 1988). Mutations in EPSI, but not in EPSII, result in decreased virulence, probably because EPSII mutants produce EPS *in planta.*

There is evidence that EPS production in *P. solanacearum* is subject to both negative and positive regulation. We have described a potential negative regulator, *epsR*, and Tim Denny's group has described a potential candidate for a positive regulator of EPS expression, the product of the *phcA* gene, which can complement production in some but not all spontaneous EPS mutants of *P. solanacearum* (Brumbley and Denny 1990). Thus, we are in a very good position to characterise the EPS biosynthetic genes and their regulation. This information will be extremely useful in deciphering the physiological interactions of the bacterium with its hosts.

As a final step in the colonisation of the xylem tissues, the bacterium must alter the nutritional status of the xylem fluids. There is little question that the

bacterium accomplishes this through the production of growth regulators. We know that the bacterium is an efficient producer of 3-indolyl-acetic acid (IAA) and early investigations in our laboratory defined the pathways that it utilises to synthesise IAA from its precursor, tryptophan (Phelps and Sequeira 1968). We also know that it produces substantial amounts of the cytokinin. trans-zeatin (Akiyoshi et al. 1987), and of ethylene (Bonn et al. 1975). The picture that emerges from all this work is as follows: IAA and cytokinin stimulate the xylem parenchyma to redifferentiate and divide; this creates a new zone of meristematic activity that reroutes nutrients into the xylem parenchyma and, ultimately, into the infected xylem. Ethylene, at the same time, causes a strong shift in host tissues toward increased synthesis of aromatic compounds, including tryptophan and IAA, and of phenolic compounds that inhibit IAA oxidase, thus allowing accumulation of IAA in the infection court (Sequeira 1973). These changes are evidenced, at the histological level, by hyperplasia and hypertrophy of the xylem parenchyma, which results in crushing of young tracheids in many instances. At the biochemical level, these changes are associated with a rapid increase in sugars and amino acids at the infection court (Pegg and Sequeira 1968).

The coordinated phenomena that I have described are based on very old observations. It is time now to determine whether these biochemical interpretations are correct. The most logical approach is via the use of mutagenesis, cloning, and functional analysis of the genes involved in synthesis of growth regulators. The cytokinin gene of *P. solanacearum*, trans-zeatin synthase (*tzs*), has been cloned and sequenced (Akiyoshi et al. 1987). It appears to be nearly identical to the cytokinin gene in *Agrobacterium tumefaciens*. Since IAA genes from other bacteria have been cloned, it should be possible, with current techniques, to generate defined auxin and cytokinin mutants, and to determine how important these substances are in virulence.

The final stages in the life cycle of the bacterium involve its lateral movement into other xylem elements, and, eventually, its release from that walled prison. One can envision that lateral movement in most plants occurs via the bordered pit pairs, which contain pit membranes that separate adjoining adjacent xylem elements. This membrane is essentially a remnant of the primary cell wall and, thus, it is susceptible to digestion by the pectinases and cellulases produced by the pathogen. Similarly, the bacterium can escape into the adjoining parenchyma through simple pits and there it can cause tissue maceration through the concerted action of pectinases, cellulases, and proteases. The lysigenous cavities that result are typical of the last stages of wilt; they are filled with bacteria, which are released into the environment upon collapse of the tissues. Perhaps more important to the life cycle of the bacterium, however, is the constant release of bacteria into the soil through the same port that allowed penetration in the first place: the points of emergence of lateral roots (Kelman and Sequeira 1965).

Epilogue

I have attempted to use the information we have today on the genetic makeup of *P. solanacearum* to draw possible pictures of its evolution through time and space, of its survival, and of its colonisation of the host. One cannot fail to be impressed by the fact that, through its long coevolution with higher plants, this bacterium has managed to develop a strong capacity to adapt to different environments. This tremendous plasticity is exhibited often in the frequent reports of new hosts and of new epidemics that continue to baffle us by their intensity and unpredictability. The ability of this bacterium to attack plants from the hot, steamy depths of the Amazon Valley to the frozen high altitudes of the Andes, never ceases to amaze me. The stability of different strains throughout large geographical areas provides an interesting contrast with its instability in culture. Or is it 'instability'? Are we merely dealing with different forms of the bacterium as it adapts to unusual environments? If so, how does it manage to switch from one stage to another? How does it acquire the ability to invade new hosts? These and many other questions will provide the excitement that we all feel as modern tools of molecular biology and bacterial genetics begin to be applied and the bacterium, slowly but surely, starts to yield some of its tightly-held secrets.

Whole Genome Analysis of *Pseudomonas*

B.W. Holloway, A.R. St G. Bowen and M.D. Escuadra*

Abstract

Genetic analysis of bacteria has been traditionally carried out by *in vivo* gene transfer techniques, principally conjugation, transduction and transformation. The advent of recombinant DNA procedures has enabled a totally new approach to be used. A combination of pulsed field gel electrophoresis (PFGE), restriction endonuclease site mapping, cosmid libraries, insertion sequence location, restriction fragment length polymorphisms, genetic probes from cloned genes and the use of computer banks of nucleotide and amino acid sequences now provide a means of whole genome mapping of any bacterium. A combined physical and genetic map has now been constructed for *Pseudomonas aeruginosa* using *SpeI*, PFGE and a wide host range vector-based cosmid library. The genome size is 5.9 kb, there are 38 *SpeI* fragments and over 100 genes have been located. This map has enabled a detailed genetic analysis of the OriC (chromosomal replication site) to be made. Similar maps of *P. putida* and *P. solanacearum* are being made but these organisms have proved to present a variety of technical difficulties not encountered in *P. aeruginosa*.In *P. putida* there is a large number of small *SpeI* fragments, making construction of the physical map difficult. In *P. solanacearum* there is abundant repetitive DNA, a complication which also makes construction of a coherent physical map more difficult. However, the knowledge so far obtained for *P. solanacearum* has helped in understanding the relationship of genes which contribute towards disease-producing characteristics and in understanding the role of acridine orange in causing genome deletions.

GENETIC analysis of microorganisms has enabled a highly sophisticated understanding of the nature of the bacterial cell and the use of such detailed genetic data is of increasing value for applied aspects of biology, especially plant–bacterial interactions and biotechnology. The history of classical microbial genetics which resulted in the discovery of gene exchange mechanisms including conjugation, transduction and transformation involved the intensive study of a few selected organisms of which *Escherichia coli* K12 was the most prominent. The need for genetic analysis of newly isolated strains of a variety of bacteria, plus the advantages of whole genome analysis, has meant that these classical techniques no longer play such an important role in bacterial genetic analysis. They have been replaced by a range of physical genetic procedures which are readily applicable to almost all bacterial genera and enable mapping of chromosomal and plasmid components by a variety of criteria including restriction sites, markers affecting phenotypic criteria and DNA sequences other than those of structural genes.

*Department of Genetics and Developmental Biology, Monash University, Clayton, Victoria 3168, Australia.

These techniques have been used for various species of *Pseudomonas* notably *P. aeruginosa*, and are now being extended to other species including *P. putida* and *P. solanacearum*. These techniques will play a seminal role in identifying the genetic components of *P. solanacearum* that determine bacterial wilt disease in plants, and the specificity of such disease by particular bacterial strains for selected hosts.

Physical Genetic Mapping

The development of techniques for the physical analysis of genetic material has been extensively documented (Sambrook et al. 1989). The techniques that are of particular use for bacteria have been discussed in two recent review articles (Krawiec and Riley 1990; Smith and Condemine 1990). The following procedures can be used for the whole genomic analysis of most bacteria.

Construction of a Genomic Library Using a Cosmid Vector

It is important to use a wide host range cosmid vector such as pLA2917 which can replicate in most Gram-negative bacteria (Allen and Hanson 1985). Compre-

hensive cosmid banks using this vector have been constructed in *P. aeruginosa* (Ratnaningsih et al. 1990), *P. putida* (A. F. Morgan, pers. comm.) and various methylotrophs (Lyon et al. 1988; Lee et al. 1991) and *P. solanacearum* (A. Bowen, M. Escuadra and B. Holloway, unpublished data). These banks have been constructed using the *Escherichia coli* K12 strain S17-1 (Simon et al. 1983) as the host. The advantage of this strain is that it has genetic material of an IncP-1 plasmid integrated into the bacterial chromosome. This enables direct transfer of pLA2917 and cloned DNA to other bacterial recipients by two parent matings. This facility is of particular value for complementation tests to identify genes on cloned chromosomal fragments. It has been found that 25 kb is a suitable size for such cloned inserts and comprehensive bacterial genome banks can be constructed provided at least 750 individual clones are selected. In practice the number of such clones isolated is usually a thousand or more.

Preparation of a Whole Genome Restriction Map

By a combination of Pulsed Field Gel Electrophoresis (PFGE) and the use of restriction enzymes with rare cutting sites, it has been possible to prepare restriction maps of whole bacterial genomes. One of the first bacteria examined in this way was *Escherichia coli* K12 using the enzymes *Not*I and *Sfi*I, resulting in an ordered sequence of the fragments produced by each enzyme (Smith et al. 1987). Similar maps have now been prepared for many bacteria, and a number have been listed by Krawiec and Riley (1990). Ideally, the number of restriction fragments should be in the range 20 to 45 to provide accurate separation of fragments in PFGE.

An important feature resulting from PFGE analysis is that it provides an accurate measurement of the genome size. Measurements have shown that, in bacteria, this ranges from 565 kb for the human pathogen *Mycoplasma genitalium* to 9454 kb for *Myxococcus xanthus*. Various *Pseudomonas* strains have been measured in this way for genome size (Ratnaningsih et al. 1990; Römling and Tümmler 1991; Grothues and Tümmler 1991) and most fall into the 5000–6000 kb range.

Construction of a Physical Genetic Map

Genes can be located on the restriction enzyme fragments by probing techniques. The first step is the screening of a cosmid bank to enable the location of genes by complementation of known mutants. If a particular cosmid clone can restore the phenotype of a mutant to wild type, then the cloned fragment can be assumed in most cases to carry the wild type allele of a homologous gene. Mutants of the homologous organism are not necessarily required for such complementation. For example, genes on individual cosmids of genome libraries of *Methylophilus viscogenes* and *Methylophilus methylotrophus* were identified by complementation of mutants of *P. aeruginosa* PAO. Essential technical features of this procedure are: firstly, that *P. aeruginosa* can express heterologous genes very efficiently, and secondly, by growth at 43°C, *P. aeruginosa* becomes restriction deficient and will accept heterologous DNA at high efficiency (Holloway 1965). Using this complementation approach it was possible to construct a preliminary map of each of these methylotrophs, a feature of this map being that the relative gene order was constructed using the wild type alleles of the methylotrophs, in contrast to the use of mutant alleles for the construction of a genetic map (Lyon et al. 1988). Thus, genes can be identified on individual cosmids and by using such characterised cosmid clones as probes against the restriction enzyme fragments, it is possible to identify the location of particular genes in terms of individual fragments.

Probing can also be carried out using either cosmids, cloned genes or oligonucleotides obtained using data derived from DNA or protein sequence banks. A feature of linkage data obtained in this way is that genes can be located which could not be mapped by traditional gene exchange procedures. For example, Smith et al. (1991) have precisely located the origin of chromosome replication (*oriC*) in *P. aeruginosa* and have demonstrated the presence of a second *ori* locus with as yet an unknown function about 10 kb away from *oriC*. It would be impossible to obtain such precise data using gene exchange procedures.

A physical and genetic map of *P. aeruginosa* is now available which identifies the relative location of *Spe*I and *Dpn*I fragments and the location on fragments of some 137 markers (Holloway et al., in press). While some of this information has been derived more easily because there is an extensive genetic map of *P. aeruginosa* (Holloway and Zhang 1989; Holloway and Carey 1992) prepared by traditional mapping procedures, there is no requirement that data be obtained by these methods and the techniques used to construct such a physical and genetic map could be used for an organism which lacks any gene exchange procedures.

Construction of a Physical Genetic Map for *P. solanacearum*

There are no adequate techniques for gene exchange in *P. solanacearum*, so the physical genetic techniques described above are ideally suited for genomic

mapping of this bacterium. Two strains have been examined, PS01 and PS1000, both isolated in Australia, both biovar 3, race 1 (Hayward, pers. comm.), PS01 isolated from potato and PS1000 from eggplant. Both can cause wilt of tomatoes using the stem inoculation procedure. A preliminary *Spe*I map has been constructed using the techniques developed in *P. aeruginosa* (Ratnaningsih et al. 1990). Thirty fragments have been identified as shown in Table 1. PS01 and PS1000 both show the same *Spe*I fragment pattern as measured by the number of fragments and their sizes.

Table 1. Sizes of *Spe*I fragments of *P. solanacearum* strains PSO1 and PS1000 obtained using the CHEF mode of PFGE.

		Genome Size	5548 kb

[a]The fragments have been designated by letters of the English alphabet based on the proposed nomenclature by Tümmler et al. (1992). Bands with identical size are inferred doublet bands based on appearance and intensity of fluorescence of the ethidium bromide stained gel.

[b]The sizes of *Spe*I fragments A-H were determined using a single pulse time of 35 seconds; *Spe*I bands I-T were determined using a single pulse time of 12.5 seconds; *Spe*I bands U-X were sized using a single pulse time of either 6 or 3 seconds; *Spe*I bands Y-AD were measured using a pulse time of 2 seconds.

To determine the linkage relationships of these fragments a library of linking clones was constructed, each clone containing a *Spe*I site. This method was used successfully by Ratnaningsih et al. (1990) in the construction of a physical map of *P. aeruginosa*. In all, 82 such linking clones were isolated in PS1000 but a comprehensive range of *Spe*I sites has not been obtained to date. A total of 16 *Spe*I junctions involving 22 *Spe*I fragments was identified. They could be arranged into six unlinked groups as shown in Figure 1. Römling and Tümmler (1991) have achieved the same result using two-dimensional PFGE.

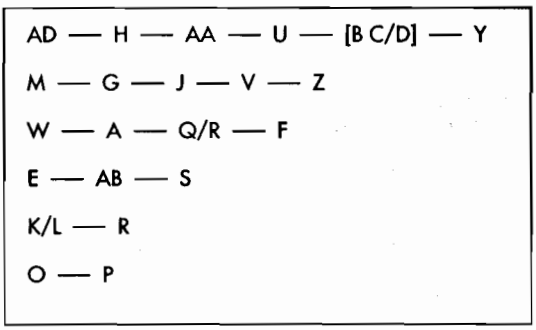

Fig. 1. Linkage arrangements of *Spe*I fragments in *P. solanacearum* PS1000. The letters refer to the fragments identified in Table 1. Fragments B, C and D have not yet been distinguished with respect to which are linked to the flanking fragments U and Y.

One of the difficulties encountered in establishing linkage of the *Spe*I fragments by cloning techniques is the presence of repetitive DNA sequences in the genome of *P. solanacearum* PS1000. Up to 60% of the *Spe*I linking clones gave hybridisation signals for a number of *Spe*I fragments, in one case eight such signals were obtained for one clone, this result arising from uncharacterised repetitive DNA. Clearly, a variety of strategies will have to be used to establish a comprehensive physical map of the *Spe*I fragments of this organism.

Individual genes have been located on individual *Spe*I fragments by probing with members of a cosmid library. A library of PS1000 was constructed using the broad host range cosmid vector pLA2917 (Allen and Hanson 1985), *E. coli* S17-1 (Simon et al. 1983) being the host for this library. The PS01 library consisted of 1000 individual cosmid clones while the PS1000 library had 2500 members. In each case the average insert size was 25–27 kb. Characterised mutant strains of *P. aeruginosa* PAO were used as recipients to identify genes on individual cosmid clones by complementation. In all, 48 different auxotrophic loci of *P. aeruginosa* were complemented by one or more cosmid clones carrying fragments of the *P. solanacearum* chromosome. Such complementation demonstrated linkage between certain markers, such linkage being identified by the fact that more than one marker could be complemented by a single cosmid clone. The extent of such linkages is shown in Table 2.

It is important to note that some of these linkage relationships differ from those found in *P. aeruginosa* and *P. putida*. For example, the close linkage of *trpA*, *trpB*, *trpF* and *leu-10* is different, as is the clustering of the histidine genes examined.

By probing with those cosmid clones on which genes had been identified by complementation it was

Table 2. Complementation linkage patterns in *P. solanacearum* PSO1000 established by cosmid complementation of *P. aeruginosa* PAO auxotrophic mutants. The prefix C indicates that linkage has been obtained by complementation (Lyon et al. 1988). Marker abbreviations are those used by Holloway and Zhang (1989).

C*trp*A – C*trp*B – C*trp*F1 – C-*leu*-10
C*arg*B – C*met*-28
C*pur*-70 – C*pur*-75 – C*his*V
C*arg*A – C*nad*-9003
C*his*I – C*his*IIA – C*his*IIB – C*his*III
C*thr*-48 – C*thr*-9001
C*aro*-1 – C*phe*-2 – C*met*-9011

possible to map some genes to particular *Spe*I fragments. The results are shown in Table 3. The extent of this physical genetic map of *P. solanacearum* will need to be extended by further probing with cosmids carrying identified genes or with cloned material.

Genomic Location of Genes of *P. solanacearum* Affecting Virulence

The cosmid banks so constructed in *P. solanacearum* have also been used for the identification and location of genes involved with extracellular polysaccharide production (EPS). It has been shown that at least one of the genes concerned with EPS synthesis is closely linked to *argA* and *nad-9003*. Three EPS regions were characterised by complementation of Tn*5*-induced Eps$^-$ mutants, restriction enzyme mapping and Southern hybridisation. A fourth EPS region was identified but not further characterised. By PFGE and Southern hybridisation using cosmids carrying *eps* markers as probes, it was possible to locate these markers on *Spe*I fragments A, W, N and F (see Table 1).

Message et al. (1978) first demonstrated that treatment of *P. solanacearum* with acridine orange resulted in mutants which had lost the ability to infect plants, as well as incurring other phenotypic changes including auxotrophy, pigment production and loss of the hypersensitive response on tobacco plants. It was subsequently shown by Boucher et al. (1988) that mutants of *P. solanacearum* resistant to acridine orange had incurred deletions in megaplasmid DNA. It was also shown that survivors of acridine orange treatment deleted *hrp* genes in all *P. solanacearum* races tested.

In the present study, mutants resistant to acridine orange were isolated and the results of Message et al. (1978) confirmed. In all, four classes of acridine orange resistant mutants were identified. Examples of classes 1 and 2 were examined by PFGE and it was demonstrated that there was a changed pattern of *Spe*I fragments. The data are shown in Table 4.

Table 3. Localisation of genetic markers on *Spe*I fragments of *P. solanacearum* by Southern hybridisation using cosmid clones as probes.

*Spe*I fragment	Markers
A/W[a]	EPSIII region
B, C/D[b]	EPSII region
F	EPSIV, rDNA[c], pgl region
E	*phe-2, aro-1*
G	*ilvB/C*
H	*met-28, proA, argB, argC*
I	*thr-48, thi-1*
J	*leu-1, leu-2, leu-10, trpA, trpB, trpF*
K/L[b]	*pyrF, pgl*, rDNA[c]
M	rDNA[c]
N	*argA, cys-1, cys-50, ilvD, nad-9003*, EPSI region
O/P[b]	*hisI, hisIIA, hisIIB, hisIII, trpC, trpD*, rDNA[c]
Q/R[b]	*pyrD*
S	*argG*
T	*hisV, pur-70, pur-75*

[a]A and W are adjoining *Spe*I fragments and the cosmid carrying the EPSIII region also includes a *Spe*I site

[b]Doublet bands of similar size

[c]Probing for ribosomal genes was carried out using the plasmid pPA10 which carries rDNA genes of *P. aeruginosa* (Housiaux et al. 1988).

Abbreviations: *arg*, arginine; *aro*, aromatic amino acids; *cys*, cysteine; EPS, extracellular polysaccharide production; *his*, histidine; *ilv*, isoleucine + valine; *leu*, leucine; *met*, methionine; *nad*, nicotinamide; *pgl*, polygalacturonase; *phe*, phenylalanine; *pro*, proline; *pur*, adenine; *pyr*, pyrimidine; rDNA, ribosomal DNA; *thi*, thiamine; *thr*, threonine; *trp*, tryptophan.

The disappearance of the characterised *Spe*I fragments listed in Table 4 was accompanied by the appearance of fragments of other sizes, but in all cases there was a loss of total genomic size. On the present data it is likely that *Spe*I fragments A, F and AC comprise part of a megaplasmid (Boucher et al. 1986). Given the linkage data in Table 3 and the association of *Spe*I fragments listed in Figure 1, it may be possible with further data to identify genes and other fragments associated with one or more megaplasmids. The potential of this approach to genomic analysis is seen by these data. Further work should clearly distinguish the *Spe*I sites of the megaplasmid components of the *P. solanacearum* genome and the location of chromosomal and extrachromosomal genes that contribute to the virulence phenotype of *P. solanacearum*. A similar type of analysis has previously been carried out with *Rhodobacter sphaeroides* to distinguish chromosomal and plasmid genomic components (Suwanto and Kaplan 1989), and Sobral et al. (1991) showed that the two megaplasmids and the chromosome of *Rhizobium meliloti* 1021 could be separated using Transverse Alternating Field Electrophoresis.

Table 4. Phenotypic and physical genomic changes in acridine orange resistant mutants of *P. solanacearum* PS01. The *Spe*I fragments referred to are those described in Table 1.

Class	Phenotype	Mutant number	*Spe*I fragment changes
1	Lacks extracellular polysaccharide production, polygalacturonase activity, auxotrophic for methionine and producing a dark brown pigment	PSO22	A, C/D[a], F, W, AC Total loss 358 kb
		PSO23	A, F, S, AC Total loss 428 kb
		PSO25	A, F, AC Total loss 519 kb
		PSO26	A, F, AC Total loss 519 kb
2	Normal extracellular polysaccharide production, but lacks polygalacturonase activity; auxotrophic for methionine and producing a dark brown pigment	PSO24	A, F, AC Total loss 428 kb
3	Lacks extracellular polysaccharide production, normal polygalacturonase activity; prototrophic with normal pigmentation	PSO21	Not examined
4	Lacks extracellular polysaccharide production, normal polygalacturonase activity; auxotrophic for serine or glycine with normal pigment production	PSO20	Not examined

[a]One of the members of this doublet is no longer present.

Discussion

The techniques for whole genome analysis of bacteria open up experimental approaches for a range of problems involving the disease-producing potential of *P. solanacearum*. It is still unclear as to the genetic differences between isolates identified as biovars (Hayward 1964) and races (Buddenhagen et al. 1962). Recently, genomic differences between race 3 (biovar 2) and other isolates were demonstrated using a probe obtained by subtractive hybridisation (Cook and Sequeira 1991). It would be highly productive to determine if these differences were confined to particular regions of the *P. solanacearum* genome. Cook and Sequeira (1991) suggest horizontal gene transfer as the cause for part of the genomic differences found in race 3, putting forward the highly interesting proposal that the differences found in race 3 specific DNA are due to a part of a prophage specific for that race. Differences of this type in which specific components of the *Pseudomonas* genome have been acquired by accretion have also been discussed by Holloway and Morgan (1986), and evidence of chromosomal acquisition of specific fragments of plasmids has been demonstrated for *P. aeruginosa* by Sinclair and Holloway (1991). In addition to the general procedures of subtractive hybridization to detect genomic differences between field isolates of *P. solanacearum*, amplification of genomic DNA using arbitrary primers (Caetano-Anollés et al. 1991) can be used to detect such differences. The sequences so identified by these and similar methods can then be localised on a physical and genetic map. By a combination of such techniques the differences between races and biovars could be precisely identified in terms of DNA sequences and hence lead to an understanding of the gene products which determine the host range of *P. solanacearum*.

One of the surprising results to come from PFGE analysis of *Pseudomonas* species is the variation of genome size in different isolates of the same species. For example, 17 isolates of *P. aeruginosa* varied in size between 4.4 and 5.4 megabases (Bautsch et al. 1988), all less than the well characterised PAO strain (5.9 Mb). For *P. putida* DSM50291, a genome size of 4.4 Mb was obtained (Grothues and Tümmler 1991), much less than the 5.9 Mb reported for the *P. putida* strain PPN (Holloway et al. 1991). The most likely explanation of these differences is that there has been acquisition of genetic material by plasmids or bacteriophages, or gross chromosomal re-arrangements such as deletions, additions or transpositions of chromosomal material have occurred, followed by errors in chromosomal DNA replication. The importance of such genomic changes needs to be considered more carefully in terms of the host specificity of *P. solanacearum* strains.

Diversity of *Pseudomonas solanacearum* and Related Bacteria in Southeast Asia

S. J. Eden-Green*

Abstract

Several studies of phenetic and genomic variation in *Pseudomonas solanacearum* have shown that biovars 3, 4 and 5 belong to a major subspecific grouping predominant in Southeast Asia. There are, however, lesser-known strains that show a closer relationship to biovars 1 and 2 of non-Southeast Asian origin. Sumatra disease of clove (*P. syzygii*) and blood disease of bananas, caused by bacteria closely related to *P. solanacearum*, are endemic to Indonesia. In the Philippines, bugtok disease causes a widespread non-lethal infection of the floral raceme in cooking bananas. Characteristics of bugtok isolates are very similar to certain strains of race 2 of *P. solanacearum* from Central America, but those of the blood disease bacterium and *P. syzygii* are unique.

DISTINCTIVE features of isolates of *Pseudomonas solanacearum* from southern Asia were recognised many years ago and isolates were formerly given the subspecific status 'var *asiaticum*' (Kelman 1953). Although this designation is no longer recognised, it was based on metabolic properties of biovar 3 and accords with the predominance of strains of this and related biovars 4 and 5 in Asia (Hayward 1991). This report describes some lesser-known *P. solanacearum*-related pathogens from Southeast Asia and discusses their significance.

Sumatra Disease of Cloves

The early history and determination of bacterial etiology of Sumatra disease of cloves have been described by Waller and Sitepu (1972) and Hunt et al. (1987). The pathogen was thought at first to be related to fastidious xylem-limited bacteria of the genus *Xylella*, but was subsequently characterised as a new species, *P. syzygii*, closely related to *P. solanacearum* (Roberts et al. 1990). The bacterium affects only clove and a few other species of *Myrtaceae*, and is transmitted by xylem-feeding insects of the genus *Hindola* (Eden-Green et al. 1992). The disease is known only in Sumatra and Java and is thought to have evolved in indigenous forest host(s) (Lomer et al. 1992). *P. solanacearum* has also been isolated occasionally from clove trees, but is not specifically associated with Sumatra disease (Eden-Green and Adhi 1987).

Blood Disease

Blood disease was described about 80 years ago (Gaumann 1921, 1923), when it caused the abandonment of newly-established dessert banana plantations in the Indonesian island of Sulawesi (formerly Celebes). The disease was apparently endemic to the island and the causal agent was described as '*P. celebensis*'. There do not appear to have been further reports of the disease until it was identified in West Java in 1987 (Eden-Green and Sastraatmadja 1990). Symptoms are similar to those of moko and include leaf yellowing, flaccidity and collapse, internal reddish-brown discolouration of fruits and vascular tissues and exudation of bacterial ooze from the latter. Infection is systemic and may spread throughout the mat. Inflorescence symptoms typical of insect-borne infection are often seen in varieties with dehiscent bracts and this mode of transmission probably accounts for the rapid spread of blood disease in Java. The disease now poses a significant threat to neighbouring islands.

*Natural Resources Institute, Chatham, Kent ME4 4TB, UK.

Bugtok Disease

Bugtok or tapurok disease in the Philippines was first reported by Roperos (1965) and is widespread in cooking bananas such as saba and cardaba (Zehr and Davide 1969; Soguilon 1990). In contrast to both blood disease and moko disease—the latter was reportedly introduced to southern Mindanao in 1969 (Buddenhagen 1986)—bugtok is incompletely systemic and symptoms are typically confined to the floral raceme. Affected fruits are discoloured red or brown but vascular discolouration does not usually extend far into the fruit stem. The disease is not thought to be spread in planting material and the normal route of infection is via the inflorescence. Bugtok disease causes very high losses of cooking bananas in some areas but, although the causal bacterium is pathogenic to dwarf Cavendish bananas by experimental inoculation, the disease is not recognised as such in dessert banana plantations.

Bacteriological Characteristics

Preliminary characteristics of the causal bacteria showed that bugtok isolates were very similar to *P. solanacearum* and differed from blood disease bacterium (BDB) and *P. syzygii* in several respects. All isolates of BDB produced small, non-fluidal colonies on TZC and other commonly used media, but special media formulations had to be developed for *P. syzygii*. All these organisms could be grown on a simple mineral salts medium and a more extensive comparsion of isolates was based on their ability to utilise a range of single carbon energy sources. A numerical analysis of results of more than 40 phenotypic properties (Eden-Green, unpublished data) showed that *P. syzygii* and blood-disease isolates formed discrete phenons, whereas bugtok strains could not be distinguished from moko isolates of *P. solanacearum* (Fig. 1).

Pathogenicity tests with isolates from banana, using tissue-cultured banana plantlets and tomato, eggplant and tobacco seedlings, showed that bugtok and moko isolates were pathogenic to both banana and solanaceous hosts, whereas BDB isolates produced symptoms only in banana.

Discussion

Bacteriological characteristics clearly distinguished strains of *P. syzygii* and BDB from biovars of *P. solanacearum*, and results of nucleic acid studies (Cook et al. 1991; Seal et al. 1992) support the view that these organisms are closely related to *P. solanacearum* but have probably evolved independently in Indonesia. Further characterisation may justify reinstatement of species status for the BDB.

In contrast, characteristics of bugtok isolates were typical of *P. solanacearum*. The close genomic similarities to certain moko strains from Central America suggest either that moko was introduced to the Philippines earlier than previously supposed or that, despite evidence to the contrary (Buddenhagen 1960; Sequeira and Averre 1961), Central American strains could have originated in the Philippines. Further studies are required to resolve this question.

There are considerable differences in the symptoms, distribution and epidemiology of bugtok and moko diseases in the Philippines and it might be thought surprising to suggest that both diseases are caused by the same organism. However, the ecology of the two diseases is quite distinct. Moko is a problem in large monocultures of Dwarf Cavendish bananas where intensive cultivation practices encourage mechanical transmission and persistence in soil, but insect-borne transmission via inflorescences is unlikely. In contrast, smallholder cultivation is largely of non-dessert varieties which are highly vulnerable to insect transmission and are often grown under shifting cultivation. It thus seems plausible to suppose that the same strain of *P. solanacearum* may be responsible for the two disease syndromes under different ecological conditions.

Identification and Characterisation of *Pseudomonas solanacearum* Using Metabolic Profiles

R. Black and A. Sweetmore*

Abstract

The studies reported here were part of a wider program of developing appropriate diagnostic systems for plant clinics in less developed countries. Metabolic profiles of 64 isolates of *Pseudomonas solanacearum* from different hosts and geographical areas, five isolates of *P. syzygii* (Sumatra disease of cloves) and four isolates of blood disease bacterium (BDB) were produced using the 95-substrate Biolog system of microplates. All but five of the isolates of *P. solanacearum* were correctly identified when matched against the system's MicroLog Gram Negative (GN) database. *P. syzygii* and BDB were not included in the database, but the isolates of the former appeared close to *P. solanacearum*, while those of the latter had a characteristic profile. Metabolic profiles for each isolate were not completely consistent within and between experiments but sufficiently consistent results were obtained for identification purposes. On this basis, it was possible to identify some substrates used by all or most of the isolates tested, and others that had differential value. The reactions to the biovar substrates did not completely distinguish the isolates of *P. solanacearum* to biovar but several overall profiles could be used to differentiate biovars and other subspecific groups. Alternative software to that supplied by Biolog may be used to identify bacteria from the microtitre plate results, leading to the possibility of a cost-effective customised database of tropical and sub-tropical plant bacteria.

As part of a wider program of providing support to diagnostic and advisory services (plant clinics) in less-developed countries, commercially available systems for identification and characterisation of plant pathogenic bacteria have been evaluated. In this work, special attention was given to *Pseudomonas solanacearum* and related bacteria. Apart from the global importance of *P. solanacearum*, there are several types of bacterial wilt specific to Southeast Asia: bugtok and blood disease of *Musa* (Eden-Green and Sastraatmadja 1990) (the pathogen of the latter designated as '*Pseudomonas celebense*') and Sumatra disease of clove (*P. syzygii*; Roberts et al. 1990).

Serological and molecular diagnostics have great potential for the identification and characterisation of bacterial wilt pathogens. However, these organisms will still need to be isolated, identified and characterised for studies of pathogenicity and screening for host resistance. The Biolog system, based on a microtitre plate with 95 different substrates, is marketed as a complete identification system for plant pathogenic and other bacteria (Bochner and Savagrau 1977; Bochner 1989). A tetrazolium dye is used to indicate positive substrate reactions which may be read by eye or with a plate reader. Each taxon reportedly has unique metabolic profiles of substrate reactions which enable identification against a database of standard profiles. In this study, it was assumed that there would be sufficient redundancy among the substrates to permit characterisation of isolates of *P. solanacearum* below the species level. The API 50 series of strips (API Systems S.A.) is designed primarily for metabolic studies of bacteria rather than identification. Use of substrates is indicated by either a colour reaction (acid production) or turbidity from growth. The API 50CH set of strips with 49 carbohydrates was considered suitable for study of *P. solanacearum* and related bacteria. All six of the substrates necessary for determining the biovar of *P. solanacearum* (Hayward 1964) are contained in the API 50CH kits. The Biolog GN plate contains all but dulcitol.

The Biolog plates are used with computer software to record the substrate reactions and compare with profiles in the database. In addition to the software supplied by the manufacturers, the Bacterial Identifier program (Blackwell Scientific Publications Ltd) was evaluated for performing these functions.

Materials and Methods

Cultures of bacteria

Details of isolates of *P. solanacearum* and related bacteria are given in Table 1. Isolates were obtained from Rothamsted Experimental Station, Herts, U.K. and are referred to by the numbering in the RES collection. The cultures were stored in distilled water, with backup in 20% glycerol at –80° C. For the Biolog system, log-phase cultures were prepared by overnight incubation at room temperature on a shaking incubator in Oxoid nutrient broth (or for *P. syzygii*, a medium based on 7.5 g/L Difco casamino acids). For API 50CH plates, 24–48 hour cultures on nutrient agar were used to prepare a suspension of a suitable inoculation medium.

Biolog system

Inoculation of GN plates. To prepare inoculum, exogenous nutrients were washed off by centrifuging approximately 20 mL of culture three times in 25 mL disposable sterile universal bottles at 4000 r.p.m. and 15°C for 30 min, resuspending with 20 mL sterile distilled water each time. The final resuspension was checked for turbidity in the target range OD_{590} 0.4–0.6, diluting if necessary. Each well was inoculated with 150 µL of suspension using an eight-channel pipette and the plates were incubated at 28° C overnight. For blood disease bacterium (BDB), plates were incubated for up to five days at 28°C.

Reading of plates. After initial tests to compare accuracy of reading plates by eye and with a microtitre plate reader, all readings were done by the latter method (Anthos 2001, 590 nm filter). The plate reader was controlled and absorbance readings interpreted by ELISA LITE plate-reading software (Meddata Inc.) into negative, positive and borderline substrate use (based on intensity of reaction). For plates with low control (A1) well and low background, a data reduction template based on recommendations from Biolog was used with threshold values for borderline and positive of (A1 × 1.4) and (A1 × 2.1), respectively. With a high background, absolute thresholds were used: borderline 1.3, positive 1.6. Occasionally, no sensible result would be obtained with the template appropriate to the condition of the plate, whereas the other template would yield a meaningful result.

Identification of bacteria. Substrate reactions were fed manually into the MicroLog 1 program (Release 3.01), coupled with the MicroLog Gram-negative (GN) database (Version 3.00) and the resultant identification noted. (The program takes account of borderline results.) A matrix of the 96 wells was also set up with the Bacterial Identifier program (Blackwell Scientific Publications) to compare well reactions against a database of profiles of a representative range of plant pathogenic bacteria and saprophytes.

Analysis of metabolic profiles. Cluster analysis of substrate reactions was done with the NTSYS-pc program, version 1.60 (Applied Biostatistics Inc.).

API 50 CH system

To use API 50 strips a bacterial suspension is made up in an inoculation medium which is then pipetted into the substrate wells. Substrate use is detected by eye, either by a colour change signifying acid production, or by the presence of turbidity signifying growth. Several different inoculation media were tried without obtaining any growth or colour change in the strips with several isolates of *P. solanacearum*, including: distilled water; Ayers, Rupp and Johnson medium; and API 50 CHE medium. Finally, an inoculation medium based on API CHE without the phenol red indicator was found to be suitable. API 50CH strips were incubated at 28°C for up to 5 days.

Results and Discussion

Identification with Biolog system

Preliminary work with *P. solanacearum* and other bacteria investigated the reproducibility of results. Using replicates and repeats on separate occasions, it was found that variation could occur in several substrates, as reported previously (Hartung and Civerolo 1991), but there was sufficient consistency for purposes of identification. Some differences in substrates reactions occurred between distilled water and Ringer's as inoculation media but neither gave consistently superior identification. In the interests of simplicity and making the system as accessible as possible, distilled water was adopted as standard without replication. With the release of the new GN database, the manufacturers now recommend trypticase soy broth for inoculum preparation, but because it is readily available, nutrient broth was used in this work wherever possible.

The results obtained with the Biolog system are given in Table 1. An isolate is considered identified to a given species in the database when the arbitrary identification threshold (similarity) of 0.500 is reached. All but 5 of the 64 isolates of *P. solanacearum* (92%) were correctly identified to species. The system was able to distinguish two sub-isolates of R156, one fluidal and one non-fluidal, both isolated from Moko-affected *Musa*. Of the four other isolates which were not identified or incompletely identified, one (R598) used an unusually wide range of metabolites, while the others were unusually restricted in metabolic capabilities. BDB is not included in the GN database; isolates were consistently misidentified as related to

Acinetobacter calcoaceticus. Neither is *P. syzygii* in the database, but generally these isolates were identified as a *P. solanacearum*-like species. It is possible that some metabolic activities were repressed when the bacteria were grown in casamino acids medium.

Overall metabolic profiles

Metabolic profiles of taxa were produced by recording the percentage of isolates showing full positive well reactions. The substrates in the Biolog GN plate and the profiles for *P. solanacearum*, BDB and *P. syzygii* are given in Figure 1. In the GN database, there are two profiles for *P. solanacearum*: *P. solanacearum* A' and '*P. solanacearum* B'. All the isolates tested here related to *P. solanacearum* A. The profile of *P. solanacearum* B contains fewer positive substrates and is quite unrepresentative of the isolates tested in this work.

BDB had a characteristic profile resembling part of the *P. solanacearum* profile, with no additional substrates used. It is interesting to note that *P. syzygii*, which is recognised as a separate species (Roberts et al. 1990), appears closer metabolically to *P. solanacearum* than BDB which is not yet recognised as a separate species.

Substrates used by *P. solanacearum* could be conveniently divided into those used by most or all of the isolates (>84%), substrates used by less than 20% of the isolates and those used by approximately 25–70% of isolates ('variable substrates').

Characterisation of isolates

Biovars. The correspondence of metabolic profiles to the accepted biovars of *P. solanacearum* (Hayward 1964) is given in Appendix 1. Biovars are as assigned in the Rothamsted collection. Also included are trehalose and m-inositol, which are among substrates used by the N2 biovar (Hayward et al. 1990), and arabitol, which was used differentially. The results are summarised in Table 2 as profiles, excluding cellobiose and lactose to which no isolates gave a full positive reaction. The Biolog plates register only use of the substrates and not acid production as in the true biovar tests. In any case, the standard biovar test includes a carbon source (peptone) without which *P. solanacearum* cannot use the disaccharides. Clearly, substrate reactions for maltose, cellobiose and lactose in the Biolog plate give no indication of biovar. Any positive reaction in the wells is probably due to cometabolism of other carbon sources such as residual intracellular reserves or dead bacterial cells. However, biovars 3 and 4 were distinguishable from the other biovars by their use of mannitol, sorbitol and also arabitol. A single isolate of those given as biovar 1 (R285) was positive for both mannitol and sorbitol. As this isolate was from potato, it is suggested that it may in fact belong to biovar 3. Trehalose and m-inositol were used by all N2 isolates but only by a minority of biovar 2 isolates.

A selection of isolates from different biovars was processed on API 50CH strips. Biovar substrates were among the very few which were used over a 5-day period. Several of the biovar 1 isolates were negative for all substrates, so there was no indication that any growth had occurred. Interpretation of the biovar of the other isolates tested was inconsistent.

Patterns of use of other substrates. The use of the other 19 'variable' substrates was analysed for further differential patterns. The profiles of the eight most significant are summarised in Table 3. Individual isolates of *P. solanacearum* on different hosts may not

Biovar III	10	60	100	100	30	50	70
Biovar IV	9	13	100	88	13	50	63
Biovar V	2	0	0	0	0	100	50
P. syzygii	5	0	0	0	0	0	0

be distinguishable by substrate reactions, but there are differences in overall profiles between isolates from *Musa* and those from other hosts. Similarly, biovars 3 and 4 had different profiles. Biovar 2 is distinguished by the poor metabolism of several substrates. [R295 is given as a doubtful biovar 2 isolate in the Rothamsted list and given as biovar 3 by Cook et al. (1989). BDB is given as biovar 1 but it appears metabolically to be closer to biovar 5. For the limited number of isolates of *P. syzygii* studied, the results are not inconsistent with the findings of Roberts et al. (1990)].

The distinct patterns in utilisation of non-biovar substrates are supported by the results of cluster analysis. Figure 2 shows the dendrogram resulting from cluster analysis of the substrate reactions of all 19 'variable' substrates. In the two major divisions of the dendrogram (I and II), all the isolates of *P. syzygii* and BDB fall in division I, while all but two of the 19 isolates of biovars 3 and 4 fall in division II. At the highest level of similarity, the clusterings are not inconsistent with the RFLP groups of Cook et al. (1991) and consensus primer groups of Seal et al. (1993). Of particular note is the tendency of isolates of biovar N2 to cluster separately from isolates of biovar 2, and the clustering of many *Musa* isolates separately from other biovar 1 isolates. These results were obtained from using the Biolog system primarily for identification, without refinement of conditions to standardise responses. With this in mind, the use of this system to characterise isolates of *P. solanacearum* according to host or other variables seems promising.

Towards a customised database for tropical bacteria

The Biolog system appears to offer a robust means of identifying isolates of *P. solanacearum* by matching to a database of known bacteria. However, the inclusion of the unrepresentative '*P. solanacearum* B' profile in

Table 3. Patterns of substrate use indicated by further variable substrates to identify biovars of *Pseudomonas solanacearum*.

the database distorts the identification process (see below) and BDB and *P. syzygii* are missing from the database. Common saprophytes and other non-pathogenic bacteria commonly associated with plants are not well represented in the Biolog databases. In some versions of the Biolog software, user-defined profiles may be used and customised databases constructed. However, such versions are at present only available in a package combined with plate-reading software; such a package was not purchased by this laboratory because general plate-reading software was already available and the cost was several times that of the non-expandable MicroLog 1 program.

An alternative was to use the Bacterial Identifier software package, by Ward (1992). A matrix of the substrates in the Biolog plate was constructed instead of an array of conventional tests for which the program was originally designed. A working database was made by adding profiles of a number of other bacteria as well as *P. solanacearum, P. syzygii* and BDB. Identifications are made in a similar way to the Biolog software by entering well reactions (borderline results are entered as missing values). The major advantage of Bacterial Identifier is that it provides an alterable or expandable database for approximately the same cost as the non-expandable MicroLog 1 system. Bacterial Identifier also gives more information in cases where there is no positive identification and has the added advantage that individual sets of results can be stored. When a model pattern for *P. solanacearum* based on the substrates used by at least 84% of the isolates was entered in the Biolog identification program, there was no identification, but a similarity of 0.457 to *P. solanacearum* B. With Bacterial Identifier and a database containing the 'A' and 'B' profiles, this model isolate was identified satisfactorily as the 'A' isolate.

A single comprehensive profile for *P. solanacearum* may offer the best way of identifying this taxon. Discrimination of biovars or other sub-specific groups could be accomplished by analysis of metabolic profiles. However, the best way of proceeding needs to be evaluated by testing a series of 'unknown' isolates against differently arranged profiles. On completion of the wider project, a database of Biolog profiles and the matrix of substrates will be sent to the publishers of Bacterial Identifier with a view to future distribution.

Conclusions

Approximately 92% of all the isolates of *P. solanacearum* tested were identified correctly with the Biolog system. Some interpretation of biovars is possible, with these and other sub-divisions becoming apparent on analysis of substrate patterns. With refinement of conditions of preparation and incubation, the Biolog system could become a powerful tool for investigating the metabolism of *P. solanacearum* and related species. There is a need for representative profiles of these bacteria to be established in a database of profiles of tropical and sub-tropical bacteria from plants (including saprophytes). Alternative software to Biolog's own can be used to identify bacteria on the basis of results from the Biolog plates. This, combined with the Biolog plate system, could be a cost-effective means of identifying *P. solanacearum* in otherwise poorly equipped and supplied laboratories.

Acknowledgments

This work was funded under the Program Development Commission of the Overseas Development Administration (Project I0037). The authors acknowledge the supply of a review copy of Bacterial Identifier on extended loan from Blackwell Scientific Publishers and are grateful to Dr Keith Shawe for assistance with cluster analysis and Ms Amanda Burstow for technical assistance.

The use of the Biolog Identification System for the Rapid Identification of Plant Pathogenic Pseudomonads

Xiang Li and A.C. Hayward*

Abstract

The Biolog Identification System (Biolog, Inc., Hayward, California, USA) with microclimate 2 software was successfully applied within 24 hours to identify type and reference strains of *Pseudomonas solanacearum* (n=15) including biovars 1, 2, 3 and 4, *P. andropogonis* (n=17), *P. caryophylli* (n=1), *P. cepacia* (n=5), *P. gladioli* pv.*gladioli* (n=2), *P. pseudomallei* (n=2), *P. pickettii* (n=1), *P. rubrisulbabicans* (n=1) and other pseudomonads and xanthomonads. Data analysis using the Taxan program (University of Maryland, MD, USA) showed that *P. solanacearum* isolates separated into two divisions equivalent to those obtained on restriction fragment-length polymorphism (RFLP) by other scientists. Biovar 1 including the type strain (K60) and biovar 2 comprised one division and shared 81.6% similarity; the other division containing biovars 3 and 4 shared 84.6% similarity. The two divisions were joined at 72.2% similarity. *P. pickettii* showed 66.6% similarity with *P. solanacearum*, whereas the remaining rRNA group II species joined with *P. pickettii* and *P. solanacearum* at a 55.2% level of similarity. We conclude that the Biolog Identification System is a useful tool for the rapid identification of nonfluorescent plant pathogenic pseudomonads including *P. solanacearum*.

MINIATURISED identification systems such as the API System have been widely and successfully used for the identification of clinically important bacteria,but their use in plant bacteriology has hitherto been somewhat limited. Whereas the API 20E series is designed for the diagnosis of human diseases caused by members of Enterobacteriaceae, API 20NE is used for bacteria of environmental origins. When the authors tested four strains of *Pseudomonas andropogonis* (E.F. Smith) Stapp from various hosts using API 20NE the results were identical, although identification was not achieved (unpublished data) which suggests limited application at present for plant pathogenic bacteria.

Biolog Identification System (BI System)—Biolog, Inc. Hayward, California, USA—serves for the identification of 569 taxa of Gram-negative and 223 Gram-positive bacteria. The identification is based on the respiratory activity developing on a panel of 95 different carbon sources in a microtitre plate within a 4 hour and 16–24 hour incubation period, leading to a tetrazolium-based colour change. Organisms are identified according to the reaction pattern using a computer driven by MicroLog™ 2 software. There are no reports on the use of this system in identification of plant pathogenic pseudomonads. We report here on the application of BI System rapid identification of plant pathogenic pseudomonads, including *P. solanacearum* E.F. Smith

*Department of Microbiology, University of Queensland, Queensland 4072, Australia

Materials and Methods

Bacteria tested

Strains and isolates of *P. andropogonis* and *P. solanacearum* tested are listed in Tables 1 and 2. Other bacterial species listed in Table 3 were obtained from the Australian Collection of Microorganisms, University of Queensland (ACM) except for *P. caryophylli* (Burkholder) Starr and Burkholder 2313Q (NCPPB2151) which was obtained from Barbara Wood of the Queensland Department of Primary Industries (QDPI) and for *P. cepacia* (Burkholder) which was supplied by Paula Cathcart. All cultures except strains of *P. solanacearum* were previously identified using conventional bacteriological tests and SDS-PAGE of whole cell proteins. Strains and isolates of *P. andropogonis* were also identified using immunofluorescence assay with monoclonal antibodies (Li et al. 1993).

Biolog system

Biolog plates were obtained from Sigma Pharmaceuticals Pty. Ltd., Clayton, Victoria, Australia. The procedure followed the manufacturer's instructions except that the bacteria were suspended in 2 mL sterile distilled water (SDW) with the concentration corresponding to an OD. of 1.0 at 540 nm. The suspensions were further diluted with 15 mL of SDW before distribution into the Biolog plates. After 24 hours incubation at 28°C, results were read using a titre reader (Flow laboratories). A final reading for strains of *P. solanacearum* was made from plates kept for two weeks at room temperature (20–25°C).

The results were analysed and interpreted in two ways: basic identification results were obtained by manual input of the data into a computer driven by MicroLog™ 2 software; and negative and positive

results obtained in two weeks for *P. solanacearum* and 24 hours for other bacteria were assigned a binary score of 0 and 1, respectively. The Taxan program (University of Maryland, MD, USA) with Jaccard coefficients and unweighted average linkage clustering was used to generate a similarity matrix.

Results and Discussion

Of the 49 strains representing 12 species of bacteria tested, 47 strains (96%) were correctly identified at the species level (Table 3), which appears to be more efficient than that obtained using the API Rapid NFT system (Breschel and Singleton 1992).

Fifteen strains of *P. solanacearum* belonging to four different biovars were tested. Correct identification was obtained at species level in all cases after incubation for 16–24 hours. Figure 1 displays the similarity matrix of 15 strains belonging to biovars 1, 2, 3 and 4 after plates were kept for 2 weeks at room temperature. *P. solanacearum* strains separated into two divisions equivalent to those obtained on restriction fragment-length polymorphism (RFLP) by Cook et al. (1989) and restriction enzyme analysis (REA) by M. Gillings (pers. comm. 1991). Biovar 1, including the type strain K60, and biovar 2 shared 81.6% similarity in division 1; and division 2 containing biovars 3 and 4 shared 84.9% similarity. The two divisions fused at 72.2% similarity. *P. pickettii* showed 66.6% similarity with *P. solanacearum*. *P. pickettii* and *P. solanacearum* have close similarities in phenotypic properties (Hayward 1991),

as well as in whole cell fatty acid analysis (Janse 1991). Both species differed from the other rRNA group II pseudomonads, such as *P. caryophylli* and *P. gladioli*, in lacing two ornithine amide lipids (Galbraith and Wilkinson 1991), and form a separate subgroup within the rRNA group II pseudomonads on the basis of rRNA–DNA hybridisation (Palleroni et al. 1973; Palleroni 1984). The other rRNA group II pseudomonads tested, including *P. caryophylli*, *P. cepacia*, *P. gladioli* Severini and *P. pseudomallei* (Whitmore) Haynes, formed another group at a similarity level of 67.4%—see Figure 2 in this study. Because of their close phenotypic relationship, these strains could not be further subdivided.

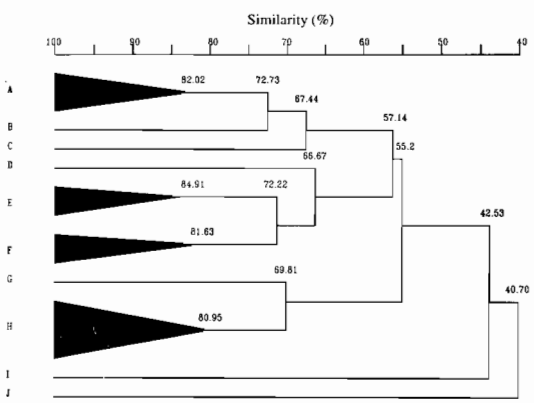

Fig. 1. Dendrogram generated from Biolog Identification System using Taxan with Jaccard coefficients and unweighted average linkage clustering. A: Strains of *Pesudomonas cepacia* and *P. gladioli* pv. *gladioli*. B: *P. caryophyulli*. C: *P. pseudomallei*. D: *P. pickettii*. E: Biovars 3 & 4 of *P. solanacearum*. F: Biovars 1 & 2 of *P. solanacearum*. G: Strain of *P. rubrisubalbicans*. H: strains of *P. andropogonis*. I: *P. rubrilineans*. J: *X. campestris* pv. *campestris*.

Seventeen strains of *P. andropogonis* isolated originally from 12 different host plants were identified as *P. andropogonis* (n = 14) and *P. woodsii* (n = 3). These two species were always listed as the top two species in the list of 10 most closely related species given on analysis of the data generated for each of the 17 strains of *P. andropogonis*. It is widely accepted that *P. woodsii* (Smith) Stevens is a later synonym of *P. andropogonis* (Hayward 1983). The results of identification by the BI System were in agreement with other results such as conventional bacteriological tests, whole cell protein profiles (data not shown), and immunofluorescence assay with monoclonal antibodies (Li et al. 1993), and showed that these strains of *P. andropogonis* were almost identical. There were no major differences in the profiles obtained for *P. andropogonis* strains in expired and unexpired Biolog plates (data not shown).

Strain ACM 2552 received as *P. rubrilileans* (Lee et al.) Stapp was identified as *P. avenae* Manns in this study, which supports the proposal that *P. rubrilileans* and *P. avenae* are synonymous (Ramundo and Claflin 1990).

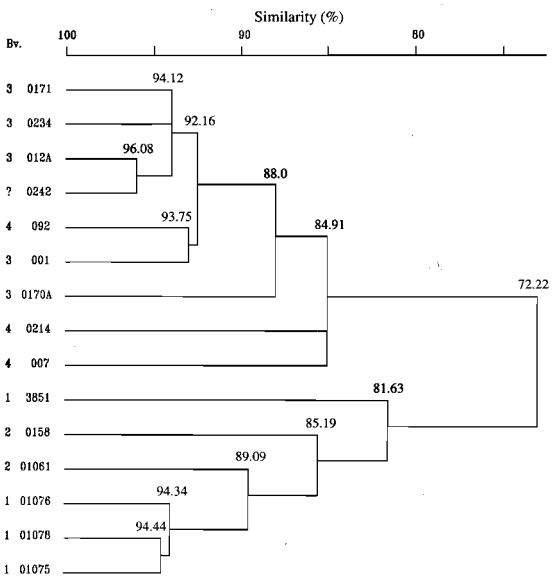

Fig. 2. Dendrogram of strains of *Pesudomonas solanacearum* in Biolog Identification System using Taxan program with Jaccard coefficients and unweighted average linkage clustering.

ACM 978 is an authentic culture of *P. rubrisubalbicans* (Christopher and Edgerton) Krasil, Nikov, a species which is not yet included in the MicroLog™ 2 software data base. The strain shared 69.8% similarity with *P. andropogonis*. Both *P. rubrisubalbicans* and *P. andropogonis* were recently included in the rRNA group II pseudomonads (De Vos et al. 1985). Both species formed a separate subgroup in the similarity matrix (Fig. 1).

Although the identifications of *P. syringae* pv. *syringae* and *Xanthomonas campestris* pv. *campestris* were successful at species level, we failed to identify correctly at pathovar level. Both species contain a large number of pathovars (Palleroni 1984), which cannot be differentiated using standard bacteriological tests, especially *X. campestris* (Moffett and Croft 1983). To identify these pathovars using BI System, more representative isolates need to be investigated.

It is concluded that the Biolog Identification System is a useful tool for the rapid identification of plant pathogenic pseudomonads including *P. solanacearum*, with 47 strains representing 12 species of bacteria being identified to species level with an accuracy of 96%.

Acknowledgments

The expert advice and assistance of Derek Warren, Manager of SPL Diagnostics in use of the Biolog Identification System and the financial support of the University of Queensland to the first author by the award of a University of Queensland Postgraduate Research Scholarship are gratefully acknowledged. We thank Miss Barbara Wood (QDPI) and Miss Paula Cathcart (UQM) for supplying some cultures.

Classification and Identification of *Pseudomonas solanacearum* and Other Pseudomonads by Fatty Acid Profiling

D. E. Stead*

Abstract

Classification of *Pseudomonas solanacearum* and other pseudomonads by fatty acid profiling paralleled that based on nucleic acid homology. Classification of taxa in rRNA homology groups 1, 2 and 3 was made on the basis of the types of hydroxy fatty acid found. Fatty acid group 1 members (the fluorescent pseudomonads) all had 10:0 3OH and 12:0 3OH. Group 2 members (*P. solanacearum* and its allies) all had 14:0 3OH, 16:1 2OH, 16:0 2OH and 18:1 2OH. Group 3 members (now largely reclassified in *Comamonas* and *Acidovorax*) all had 10:0 3OH. *P. solanacearum* and its allies were further subdivided according to the additional presence of 16:0 3OH, present in *P. cepacia* and its allies but absent in *P. solanacearum*, *P. syzygii* and the banana blood disease bacterium. Differences in profiles of taxa within group 2 were based largely on differences in the amounts of fatty acid present rather than differences in the types of acid found, but these were sufficient for accurate differentiation at species level except for some *P. gladioli* strains which were identified as *P. cepacia*. *P. solanacearum*, *P. syzygii* and the banana blood disease bacterium and had very similar fatty acid profiles and seem to form a discrete group. Differentiation of races and biovars of *P. solanacearum* was not sufficiently accurate under the cultural conditions selected. The use of slightly older cultures on other media may allow accurate race determination. However, fatty acid profiling showed that several strains of *P. solanacearum* tested had atypical profiles although they undoubtedly belonged to this sub-group. Fatty acid profiling offers a rapid, accurate method for diagnosis of disease caused by *P. solanacearum*.

THE genus *Pseudomonas* comprises several nucleic acid homology groups worthy of genus status and recently species have been transferred to other genera including *Comamonas*, *Acidovorax*, *Sphingomonas* and *Xanthomonas* (Young et al. 1992). *Pseudomonas solanacearum* and its allies are not closely related to the fluorescent pseudomonads (Palleroni 1984).

Fatty acid profiling is now regarded as a valuable taxonomic tool and several workers have shown the value of the hydroxy fatty acids in classification of Gram-negative bacteria and especially *Pseudomonas* (Oyaizu and Komagata 1983; Stead 1992a).

Fatty acid profiling is also being increasingly used as a rapid method of strain determination, and at least one commercial system is now available and gaining credence as a rapid, accurate method for identification of bacteria including the plant pathogens (Stead et al. 1992).

Fatty acid profiling comprises culture of the strain under standard conditions, harvesting, saponification of cellular lipids, methylation, extraction and purification of resulting fatty acid methyl esters (FAMEs), gas chromatographic separation, identification and quantification of the FAMEs and finally computerised comparison of this profile with a FAME library containing a wide range of profiles of strains grown under the same conditions.

This study aimed to assess the value of fatty acid profiles for classification and identification of *P. solanacearum* and its allies in rRNA homology group 2 (Palleroni 1984).

Materials and Methods

All strains were from the National Collection of Plant Pathogenic Bacteria (NCPPB) and private collections, or were freshly isolated from imported diseased potato

*National Collection of Plant Pathogenic Bacteria, Central Science Laboratory, MAFF, Hatching Green, Harpenden, Hertfordshire AL5 2BD, United Kingdom

tubers. They were maintained either freeze-dried or on beads at –80°C (Protect System). Fatty acid profiles were prepared by the method of Stead (1992b) from 24 hour trypticase soy agar plates (28°C) for all strains except for *Pseudomonas symploci* (48 hours on potato dextrose agar), *P. syzygii* (6 days on casein salts agar) and the banana blood disease bacterium (48 hours on trypticase soy agar). Identification by comparison with profile libraries was made using the Microbial Identification System (MIDI), Delaware, USA. Profile libraries and dendrogram analyses were prepared using Library Generation Software (MIDI).

Results

All profiles selected for further analysis had more than 50000 units of peak area to avoid diluting out minor FAMEs. All also had more than 85% and usually more than 95% of the total peak area comprised of named peaks. The major FAMEs present in each taxon in rRNA group 2 (> 0.3% of the total peak area) are presented in Figure 1. The results in Table 1 indicate the presence of hydroxy FAMEs in fatty acid profile groups 1–3 and *Xanthomonas*. Table 2 lists the main groups and taxa occurring in each of groups 1–3.

FAME profile libraries were prepared for all selected taxa and a dendrogram based on Euclidean distance prepared (Fig. 2). This showed several distinct groups. The xanthomonads were clearly differentiated. *P. solanacearum* grouped closely with *P. syzygii* and the banana blood disease bacterium. The two *Acidovorax* species grouped together, as did all the fluorescent pseudomonads and *P. corrugata*. This latter group was quite closely associated with the two *Comamonas* spp. All members of fatty acid profile group 2 clustered together although the Euclidean distances between the various sub-clusters were quite large. *P. alcaligenes* and *P. pseudoalcaligenes* clustered together but most closely to *P. caryophylli*.

Validation of the library was obtained by comparing all profiles considered for library preparation against the final library (Fig. 3). In most cases all strains of a given taxon were correctly identified, although several strains of *P. gladioli* pv. *alliicola* and *P. gladioli* pv *gladioli* were wrongly identified as *P. cepacia*. A single strain out of 130 *P. solanacearum* strains was wrongly identified as *P. syzygii*. This was strain NCPPB 1621, a potato strain from Mauritius which did not conform with biovars 1–4. The similarity index with *P. syzygii* was 0.51, considered to be too low for accurate identification.

For all other taxa, accuracy of identification was 100%. A further 50 *P. solanacearum* strains from the NCPPB or freshly isolated from imported potatoes (all race 3 isolates) were profiled and compared with this library. All were accurately identified.

Dendrograms and two-dimensional principal component plots of individual profiles of *P. solanacearum* strains representing biovars 1, 2, 3 and 4 and races 1, 2, 3, showed no differentiation at biovar level (results not shown). Although races 2 and 3 showed great homology and perhaps could be differentiated, race 1 strains showed much greater variation. This heterogeneity did not allow accurate differentiation between race 1 and the races 2 and 3. This was further reflected by the relative inaccuracies obtained during validation of a separate library containing entries from each of the races (results not shown).

Discussion

Classification of the plant pathogenic and some other pseudomonads based on hydroxy fatty acid profiles paralleled that by nucleic acid homology (Palleroni 1984; Stead 1992a) and this technique must now be considered a very reliable and simple way of determining genus within the pseudomonads. Most species in each group were also readily differentiated. Profiles were generally very similar for all taxa except for those in group 2a (*P. cepacia* and its allies). All members of this group possess a diversity of profiles that, in the author's experience are almost unique. There was great variation in the amounts of several FAMEs found in the cell membrane (16:1 cis 9, 17:0 cyclo, 18:1 cis 11) and also in the presence of some hydroxy FAMEs presumably part of the lipopolysaccharide moiety (10:0 3OH, 12:0 3OH). These low molecular weight hydroxy FAMEs are not normally present in these bacteria. So far, this qualitative and quantitative variation appears to be associated with colony morphology and pigmentation and will be discussed elsewhere. Nevertheless, the variation accounts for the large Euclidean distances between clusters of taxa within Group 2a. This type of variation is not found in members of Group 2b (*P. solanacearum* and its allies).

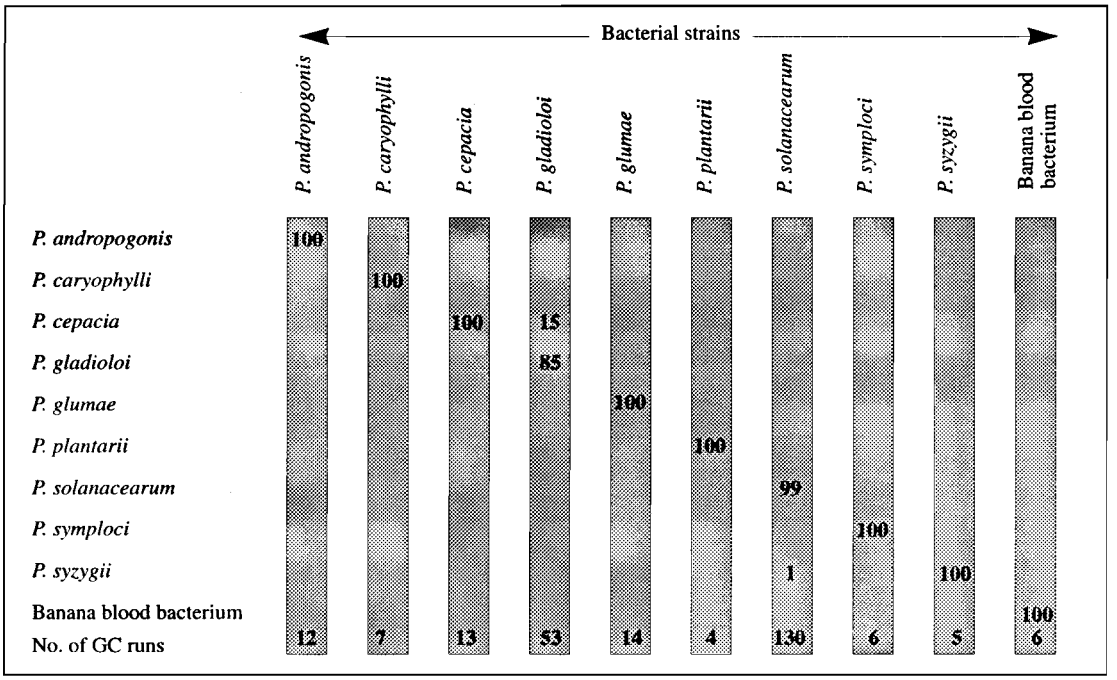

Fig. 3. Validation of 250 fatty acid profiles against a self-generated library. Values give accuracy of identification in per cent.

These fatty acid profile differences may well support a case for creation of two genera within rRNA homology group 2, one for *P. solanacearum* and its allies and another for *P. cepacia* and its allies. This has occurred in rRNA group 3 (fatty acid profile group 3) now referred to as the Comamonadaceae which contains *Comamonas* and *Acidovorax*, again both of which cluster differently in Figure 2. Dendrograms such as this must be cautiously interpreted as relatively small changes in the major cell membrane fatty acids may mask taxonomically important hydroxy acids present in relatively small amounts. This explains the relative similarities between *P. caryophylli* and the non-fluorescent members of rRNA group 1 (*P. alcaligenes* and *P. pseudo-alcaligenes*) and between the *Comamonas* spp. and the fluorescent *Pseudomonas* spp. in which the major difference is the absence in *Comamonas* of 12:0 3OH. Even in *Pseudomonas* rRNA 1 members, this FAME rarely comprises more than 5% of profiles under these cultural conditions. Nevertheless, classification of profiles based on the pattern recognition systems used in strain identification (Fig. 2) does not compromise that obtained from simple presence or absence of key hydroxy fatty acids (Table 2).

Library validation, in general showing 100% accuracy of identification, indicated the excellent potential for the use of fatty acid profiles for rapid identification at species level. Again, such validations must be treated with caution since they tend to be incestuous, in that the very profiles used in library generation are re-compared with that library. Failure to obtain a high accuracy of identification at this level would almost certainly mean decreased accuracy of identification of other strains. However, such failures usually imply either wrong classification of the taxa or, at the least, incorrect identification of some of the strains currently included in that taxon.

P. solanacearum, *P. syzygii* and the banana blood disease bacterium clustered closely together and were quite discrete from any of the other pseudomonads both in their hydroxy FAME and overall profiles (Table 1; Figs. 1 and 2). This was the case even though all three taxa were cultured under differing conditions although all were probably at a similar physiological age. It is thus difficult to be certain to what extent the differences between these taxa are due to their taxonomic differences or the cultural differences. Nevertheless, all but one of 180 *P. solanacearum* strains either in the validation or identification exercises were correctly identified.

Results not presented here showed that there was much greater variation between profiles of race 1 strains of *P. solanacearum* than those of races 2 and 3. In general, validation showed that race 3, biovar 2 strains were identified with a higher similarity index than race 1 and 2 strains. This probably reflects this homogeneity within race 3 and the fact that approximately half the 49 strains finally selected for the *P. solanacearum* library entry were race 3 isolates. Apart from the homogeneity in biovar 2 (equivalent to race 3) strains, no other relationship was noticed for biovars 1, 3 and 4. It is interesting to note that the one *P. solanacearum* strain incorrectly identified in the validation exercise did not belong to any of the four *P. solanacearum* biovars (Stead 1988). Its profile was definitely of group 2b type. In a similar study, Janse (1991) was able to demonstrate that, based on 48-hour cultures on trypticase soy agar at 28°C, four major clusters were found, corresponding to races 1, 2 and 3. The fourth cluster contained several deviating race 1, biovar 1 strains. Another study, still in progress (Stead, unpublished data), has further demonstrated that slightly older cultures (48 hour) may give more stable profiles with better differential qualities. Also, certain types of culture medium give similar profile types, but some media produced profiles that not only showed great difference in the relative amounts but also in the types of FAME present. It is hoped that improved selection of cultural conditions will further improve the taxonomic value of fatty acid profiling both in classification and identification of *P. solanacearum* strains. This value has already been demonstrated at species level and fatty acid profiling has proven to be an excellent rapid method for identification of *P. solanacearum* and many other pseudomonad species.

Results can be obtained in 24–48 hours from obtaining a pure culture. Costed over a five-year period, based on U.K. prices and including consideration of equipment, consumable and staff costs per identification, fatty acid profiling proved much more cost effective than disease diagnosis or strain identification by conventional means such as those of Lelliott and Stead (1987).

Acknowledgments

This work was funded by the Ministry of Agriculture, Fisheries and Food, Plant Health Division (projects PH14000 and SC18000). I wish to thank Mrs J. Sellwood, Mrs J. Wilson and Miss J. Hennessy for technical support and Mr J. Morrison and Mrs J. Tough and her staff for assistance with graphic design and word processing.

Serological Detection of *Pseudomonas solanacearum* by ELISA

A. Robinson*

Abstract

Several assays fo. the detection of *Pseudomonas solanacearum* are currently being developed in laboratories worldwide. Many of these techniques, although highly efficient at detecting the bacterium, require sophisticated equipment and are difficult to perform under field conditions, (e.g. the use of DNA specific probes). The Enzyme Linked Immunosorbent Assay (ELISA) does not require sophisticated equipment, is relatively inexpensive, requires the minimum of training and may be readily adapted for use in developing countries in the tropics, where the disease is prevalent. An ELISA has therefore been developed which may be used to detect the bacterium in both plant and soil samples. This ELISA has been optimised with respect to sensitivity, and is able to routinely detect bacterial levels as low as 1×10^4 cfu/mL. The assay at present uses polyclonal antibodies but recent advances in the production of *P. solanacearum* specific monoclonals mean that they will be used in the future. Such monoclonals may be produced (indefinitely) as standardised reagents, which will further improve the reliability of the assay.

BACTERIAL wilt caused by *Pseudomonas solanacearum* is a disease widely distributed in tropical, subtropical and warm temperate regions of the world. It is one of the most destructive bacterial diseases of plants and affects a wide range of economically important crops.

Research into a suitable assay for diagnosing the presence of *P. solanacearum* in plant and soil samples has been under way for a number of years. The original technique involving isolation and purification of the bacterium from the infected sample, followed by biochemical analysis (Hayward 1964), is tedious and time consuming. New techniques currently being reported, e.g. the use of non-radioactive DNA probes (Seal et al. 1992), although far more rapid, are still not suitable for use under field conditions. Immunoenzymatic techniques however, are ideal and have been used by plant virologists for the rapid identification of viruses for years. Such techniques have also been used for the diagnosis of plant pathogenic bacteria since 1978 (Cambra and López 1978; Vruggink 1978).

The serology of *P. solanacearum* has been studied by many workers, e.g. Morton et al. (1966) and Schaad et al. (1978), but only recently has this been applied to immunoenzymatic techniques. For example, an Enzyme Linked Immunosorbent Assay (ELISA) for the detection of *P. solanacearum* in potatoes was developed (Bellstedt and Van Der Merwe, unpublished data). This ELISA, as with many in the past, used polyclonal antibodies. The quantity, quality and affinity of such antibodies for a particular antigen often vary from animal to animal and, quite often, even from different bleeds of the same animal. This leads to variability in serum quality which, in turn, may lead to an unreliable assay. Polyclonals also tend to lack specificity, reacting not only with the bacterium to which they were made, but also with closely related strains.

The introduction of hybridoma technology by Köhler and Milstein (1975) provided a revolutionary advance in the production of antibodies, eliminating many of the problems associated with polyclonals. Hybridoma cells result from the fusion of B-lymphocytes (antibody producing cells) with myeloma cells (malignant cells which do not secrete antibody and are immortal in cell culture), and are therefore able to produce antibodies and be cultured indefinitely *in vitro*. Each hybridoma cell secretes identical antibodies to single antigenic determinants and may therefore be selected for secretion of the desired antibody. Such antibodies are known as monoclonal. These monoclonals have several advantages over the

*Plant Pathology Department, AFRC–IACR, Rothamsted Experimental Station, Harpenden, Herts., AL5 2JQ, U.K.

conventional polyclonals in that: (a) an unlimited quantity of antibody is available; (b) there is no variability between different batches; and (c) specific antibodies may be selected for.

This paper discusses the development of an ELISA using polyclonals and the subsequent development of monoclonals for use in the assay.

Materials and Methods

Production of polyclonal antibodies

Polyclonal antibodies were raised in Dutch-Lop cross rabbits. Initial immunisations of 5×10^8 glutaraldehyde-fixed whole bacterial cells (Allan and Kelman 1977) in Freunds' complete adjuvant (Difco Labs) were followed with an identical boost in incomplete adjuvant 4 weeks later. All injections were given intramuscularly. Rabbits were bled via the ear vein after 2 weeks and at 2–3 weekly intervals thereafter. Collected blood was allowed to clot at room temperature, separated by centrifugation (1500g for 15 minutes) and the serum collected. The amount of antibody present in the sera (the titre) was determined by ELISA.

Production of monoclonal antibodies

Immunisation Protocols. Balb-c mice were immunised intraperitoneally using one of the following protocols. An injection of 1×10^8 glutaraldehyde-fixed *P. solanacearum* cells in sterile saline was followed four weeks later by a test bleed (via the tail vein). The titres were measured by ELISA and, if sufficient, a final boost (as above) was given. In general, however, a second immunisation was required before the final boost to improve the titre (protocol a). In a second method, injection with glycoprotein antigens of *P. solanacearum* prepared from 1×10^9 bacterial cells, as described by Digat and Cambra (1976), was followed with a second identical injection after 5 weeks and a final boost 6 weeks later (protocol b). In the third method, two groups of mice (A and B) were injected with a mixture of 1×10^8 glutaraldehyde-fixed *P. syzygii* and the blood desease bacterium (BDB). Two days later group A were immunised with 20 mg/kg cyclophosphamide (which kills proliferating B and T lymphocytes) in sterile saline. This entire procedure was repeated a further three times, at two-weekly intervals. Test bleeds were taken during the intervening weeks and titres compared, with group B mice acting as controls. After a three-week rest, the mice were immunised with a mixture of 5×10^8 glutaraldehyde-fixed whole cells of *P. solanacearum* strains, followed by a final identical boost a week later (protocol c).

The Fusion. Three days after the final boost in each of the above immunisation protocols, the mice were euthanised and their spleens removed. The spleen cells were then fused with the myeloma cell line NSO, by spinning together in the presence of 50% polyethylene glycol, (Mol.Wt. 1500, Boehringer Mannheim) and 10% dimethyl sulfoxide (99.5% pure, Sigma), after the method of Kennet et al. (1978). Growth of the fused cells (hybridomas) was aided by supplementing the routine cell culture media, Dulbecco's modification of Eagle's medium (Flow Labs) containing 20% Foetal Calf Serum (Imperial Labs), with peritoneal macrophages from young mice.

Enzyme linked immunosorbent assay

There are many different ways of configuring ELISAs and a wide array of formats. The basic ELISA protocol used in this study was as described below. Any alterations to the protocol are detailed in the appropriate sections.

Incubations throughout were at either 37°C for one hour or 4°C overnight. After each stage, excess reagent was removed from the wells by 'flicking out'. The plates were then washed in three changes of PBS-Tween (phosphate buffered saline plus 0.05% v/v Tween 20), for 3 minutes each. After washing, the plates were gently 'bang dried' on tissue paper.

The routine protocol was as follows: 96 well microtitre plates were coated with a suspension of whole bacterial cells (100 µL per well) diluted to 1×10^8 cfu/mL in 0.05 M carbonate coating buffer, pH 9.6. After incubation and washing, 100 µL of either a monoclonal or polyclonal antibody diluted in blocking buffer (0.05% v/v Tween 20, 2% w/v polyvinyl pyrrolidone (PVP, Mol. Wt. 44000) and 0.5% w/v NIDO milk powder (Nestle) in phosphate buffered saline) was added and incubated. After washing, a second antibody, horseradish peroxidase conjugated rabbit anti-mouse or goat anti-rabbit (Sigma) at a 1:2000 or 1:5000 dilution, respectively, in blocking buffer, was added and incubated. Finally, 100 µL of TMB substrate (1 mg/mL 3,3',5,5'-tetramethyl-benzidine (Sigma), 0.1% v/v hydrogen peroxide and 10% v/v sodium acetate, pH 5.8 in distilled water) were added to each well and incubated at room temperature until sufficient colour developed. The reaction was stopped by adding 3 M sulphuric acid (25 µL per well). Results were assessed visually, and then quantified by reading the absorbance at 450 nm (including a turbidity correction at 650 nm), using a microtitre plate reader (ICN Flow).

Optimisation of the ELISA

Plate type. Different brands of microtitre plate differ in binding capacity and also in consistency of binding within and between plates. Several commercially available microtitre plates were therefore tested for their binding abilities using a half-log dilution series of

whole bacterial cells (1×10^8–1×10^1 cfu/mL) to determine the lowest level of bacteria detected by a polyclonal antibody (R283 diluted to 1:5000).

Coating buffer. Phosphate-buffered saline (PBS), 0.1 M citrate buffer, pH 5.0 and pH 3.0, and 0.05M carbonate buffer, pH 9.6, were all compared for their ability to bind bacteria to the microtitre plate.

Blocking buffer. Buffers containing 1% w/v Bovine Serum Albumin (BSA), 0.5% w/v BSA, 1% w/v full cream dried milk powder (DMP) or 0.5% w/v DMP with or without the presence of Tween 20 (0.05% w/v) and, or PVP (2% w/v), were compared for their ability to prevent or reduce non-specific binding throughout the ELISA.

Washings. Washings with tap water, PBS and PBS-Tween were compared using the method described previously.

Incubations. To determine the optimum incubation times of first and second antibodies, at 37°C, all combinations of 2 hours, 1 hour and 0.5 hour were compared. Optimum incubation for coating of bacteria was then determined using the optimal first and second antibody incubation periods.

ELISA design. Double antibody sandwich ELISAs (DAS) were compared with the indirect binding ELISA previously described. In DAS, microtitre plates were pre-coated with monoclonal antibody diluted 1:100 or with polyclonal antibody diluted 1:2000 in coating buffer, to 'capture' the antigen (the bacteria). The routine ELISA protocol was then followed.

Diagnostic Assay

Plant samples. One-centimetre sections were cut from the stem bases at or close to the intersection between stem and tap root, or for tubers a plug of tissue containing vascular tissue from the stolon end, of artificially inoculated and naturally infected plants. The plant tissue was macerated mechanically and resuspended at 1 mL/g in 0.05 M carbonate buffer, pH 9.6, containing 0.2% sodium sulphite (an antioxidant). The sample was allowed to settle for 30 minutes and the supernatant used to coat wells of a microtitre plate (100 µL per well) in the routine ELISA.

Soil samples. One gram samples of artificially inoculated soil were suspended in 2 mL coating buffer and shaken vigorously for 1 minute. After allowing to settle for 2 minutes, 100 µL of the supernatant was removed and used in the routine ELISA. During testing, two coating buffers were used: (i) 0.05M carbonate buffer, pH 9.6, and (ii) an amended coating buffer containing 8.3% polyvinyl pyrrolidone and 4% sodium cholate in 0.05 M carbonate buffer, pH 9.6, (S.M.D. Forde, pers. comm.).

Results

Polyclonal Antibodies

To date, three polyclonal antibodies to *P. solanacearum* (R283, R303, R608) and one to the blood disease bacterium (BDB, R230) have been raised at Rothamsted Experimental Station (Eden-Green and Robinson, unpublished). All were found by ELISA to have very high titres (Table 1). The polyclonal to BDB is as good at detecting *P. solanacearum* as those antibodies actually raised to *P. solanacearum.* All antibodies show cross-reactions to *P. syzygii,* the BDB *P. pickettii* and *P. cepacia.* They also lack specificity with respect to the biovars/races of *P. solanacearum,* detecting all isolates at 1×10^8 cfu/mL (Table 2). If the bacterial concentrations are lowered to $< 1 \times 10^5$ cfu/mL, not all isolates are detected.

Monoclonal antibodies

Monoclonal antibodies produced by immunisation protocol (a) proved to be more specific than the polyclonals, detecting only certain *P. solanacearum* isolates at 1×10^8 cfu/mL. However, cross-reactions with *P. syzygii,* the BDB and *P. pickettii* still occurred (Table 3).

Immunisation protocol (b) proved to be toxic to the mice, killing 20% within a day of the injection. Titres from the surviving mice pre-fusion were fairly low, i.e. 1:1600 compared with >1:12800 for protocol (a), and less antibody secreting hybridomas were obtained post-fusion. The few monoclonals resulting from this fusion

showed no greater specificity than those obtained with protocol (a).

During immunisation protocol (c) a comparison of the titres of cyclophosphamide treated and control mice showed that the cyclophosphamide had succeeded in removing cross-reactions. The fusion was only performed recently but, of the few monoclonals screened so far, no cross-reactions have been observed. Some interesting results regarding specificity to the biovars/races of *P. solanacearum* have also been obtained (Table 4).

Optimisation of the ELISA

Plate type. Table 5 shows the results obtained when different microtitre plates were tested. Both Griener (medium binding) and Nunc polysorp plates gave good results and were therefore used for all subsequent assays. The lowest levels of detection obtained were high due to the polyclonal antibody being diluted 1:5000.

Coating buffer. The use of different buffers to coat the bacteria onto the plate made very little difference to the end results. Carbonate buffer 0.05M, pH 9.6, was chosen for further work, however, as slightly higher absorbance readings were obtained with no increase in background levels.

Blocking buffer. Dried milk powder (0.5%) was found to decrease background levels to a greater extent than Bovine Serum Albumin (BSA). When the dried milk powder was then used with Tween 20 and polyvinyl pyrrolidone, non-specific binding was even further reduced with no detrimental effect on the sensitivity of the ELISA.

Washings. Washings done with PBS-Tween were found to be the most effective, giving lowest background readings with no loss in sensitivity.

Incubations. One-hour incubations were found to be sufficient for all stages, with 30 minutes sufficient for the second antibody.

ELISA design. Figure 1 shows the configuration of the three ELISAs which were compared. Both DAS ELISAs were found to be less sensitive than the indirect ELISA, and so were not used further.

Diagnostic Assay

Plant samples. Using the routine ELISA, *P. solanacearum* was detected in artificially inoculated and naturally infected plants, even when wilting was not apparent.

Soil samples. No bacteria were detected by the ELISA when the routine 0.05M carbonate coating buffer, pH 9.6, was used to coat the soil samples to the plates. If, however, the bacteria were extracted from the soil particles and coated directly onto the plates using a buffer containing 8.3% polyvinyl pyrrolidone and 4% sodium cholate in 0.05M carbonate buffer, pH 9.6, (MacDonald 1986), *P. solanacearum* could be detected in the soil down to levels as low as 1×10^4 cfu/mL. Bacterial levels as low as 1×10^2 cfu/mL were detected in some assays.

Discussion

The development of an ELISA to detect *P. solanacearum* has been described in this paper. This assay does not require sophisticated equipment, is relatively inexpensive and requires minimum of training, making it ideal for use in developing countries in the tropics, where the disease is prevalent. The ELISA is rapid and may be completed in as little as 3.5 hours. It has also been shown to be very sensitive, routinely detecting bacterial levels of 1×10^4 cfu/mL in both plant and soil samples.

The detailed ELISA currently uses polyclonal antibodies that have been produced relatively easily. The fact that these polyclonals cross-react with several closely related bacteria is probably of little practical significance when testing infected plant tissue, as high populations of *P. solanacearum* are likely to occur in the absence of the cross-reacting bacteria. However, in Indonesia where both *P. syzygii* and *P. solanacearum* may be found in cloves and both the BDB and *P. solanacearum* in bananas, the test would be of little use. When testing soil samples, however, cross-reactions may be a problem, as *P. pickettii* or *P. cepacia* may be present in high numbers.

Because of this cross-reactivity and the fact that polyclonals cannot be produced in unlimited quantities, a program to produce monoclonal antibodies to *P. solanacearum* was begun. It was also postulated that, by producing monoclonal antibodies, some specificity between the biovars/races of *P. solanacearum* would be obtained. Preliminary attempts at producing monoclonals by immunising mice with glutaraldehyde-fixed whole cells removed only those cross-reactions with *P. cepacia*. The monoclonals were far more selective in their detection of *P. solanacearum*, however, detecting only certain isolates. The majority of the isolates that these monoclonals detected seemed to show no specificity with regard to biovars/races.

Digat and Cambra (1976) surveyed work on the serology of *P. solanacearum* and stated that the glycoprotein antigens of *P. solanacearum* give rise to antisera that are fairly specific for differentiating races and strains. Glycoprotein antigens were therefore prepared and used to immunise mice. The antigen was found to be toxic and not highly immunogenic, giving far lower titres than those obtained from immunising with whole cells. The resulting monoclonals were also disappointing, giving rise to a similar set of monoclonals as previously obtained.

The cytotoxic drug, cyclophosphamide, has been used by several workers (e.g. Matthew and Sandrock 1987) to 'manipulate' the immune system of mice to produce monoclonals of a desired specificity. Cyclophosphamide was used here to increase the tolerance of mice to a set of antigens (namely *P. syzygii* and the BDB). Immunisation with a similar set of closely related antigens (*P. solanacearum*) followed, in an attempt to produce antibodies which would distinguish between the two groups. Positive results were seen immediately, with test bleeds detecting none of the cross-reacting strains. Monoclonals produced by this method showed no cross-reactions and detected only certain isolates of *P. solanacearum*. Varying results were found within the biovars/races, except for (a) Bugtok and Moko, which were not detected, (b) biovars 2 and 2(N) which could be distinguished from each other, and (c) race 5 which could not be detected at all. Further analysis of these monoclonals is being performed to determine if this differential activity is consistent with any other grouping system, e.g. the RFLP groups described by Cook et al. (1990).

A panel of the monoclonals produced by immunisation schedules (a) and (b), which differentially detect certain isolates of *P. solanacearum*, has been used in the ELISA. The use of such a panel has allowed *P. solanacearum* to be identified at the biovar/race level. Results obtained were satisfactory but some isolates of *P. solanacearum* tested were not detected and closely related bacteria were sometimes detected. The use of cyclophosphamide may overcome this problem, as it may be used to give rise to monoclonals of different specificity (e.g. if a mouse were first 'tolerised' to *P. solanacearum* biovars 1, 2, 3 and 4, followed by immunisation with biovar 5, biovar 5 specific monoclonals might result). Such an assay would be far superior to that developed using polyclonals, as it would not only be detecting *P. solanacearum* to the biovar/race level, but it would also be more reliable, as the monoclonals could be produced, indefinitely, as standardised reagents.

Acknowledgments

I thank Dr Simon Eden-Green for his help in producing polyclonal antibodies, Stephen Forde for producing all bacterial stocks, and Dr John Elphinstone and Phil Jones for their help and critical reading of the manuscript. This work was commissioned and funded by the Natural Resources Institute, Chatham, U.K., (project X0071), and was carried out under MAFF licence PHF1307A/74/22.

Serological and Molecular Approaches to Identification of *Pseudomonas solanacearum* Strains from *Heliconia*

A.M. Alvarez*, J. Berestecky†, J.I. Stiles*, S.A. Ferreira*, and A.A. Benedict*

Abstract

Strains of *Pseudomonas solanacearum* isolated from *Heliconia* grown on three islands of Hawaii were characterised by: pathogenicity to banana, *Heliconia*, and tomato; biochemical tests; monoclonal antibodies (mAbs); and restriction fragment length polymorphisms (RFLP). One species-specific mAb separated *P. solanacearum* from other pseudomonads as well as other genera of bacteria and was useful for the initial identification of *P. solanacearum* cultured from crude extracts of plant tissues. Strains were grouped based on serological reactivity patterns but no single mAb was uniquely associated with race 2 strains from banana or *Heliconia*. Using RFLP analysis, race 1 strains from *Heliconia* showed distinct banding patterns that differentiated them from race 2 strains from *Heliconia* and further separated them from a race 2 strain isolated from banana in Costa Rica. Two strains recovered from banana bugtok disease in the Philippines were distinct from the Costa Rican race 2 banana strain as well as the *Heliconia* strains from Hawaii.

BACTERIAL wilt, a widespread disease of tropical crops, occurs in Hawaii on tomato, pepper, ginger, and *Heliconia*. In August 1989, the bacterial wilt pathogen, *Pseudomonas solanacearum* (Smith 1896) Smith 1914 was isolated in Cairns, Queensland from diseased *Heliconia* rhizomes 3 months after release from a 3-month quarantine of plants imported from Oahu, Hawaii. One strain, identified as biovar 1, caused wilt of tissue-cultured bananas, but a second strain from *Helicona*, identified as biovar 3 or 4 caused only local necrosis and chlorosis but no wilt (I.F. Muirhead, Department of Primary Industries, Queensland, pers. comm.). In subsequent identifications, two of six strains isolated from 55 *Heliconia* plants caused severe wilt on *Musa accuminata* Colla. Williams (AAA), *M. accuminata* Sucrier (AA) and *Helicona* spp., but not on *Lycopersicon esculentum* Mill. Floradade and *Solanum melongena* L. Blackbell and were thus considered to be race 2 (Akiew and Hyde 1992). Further tests confirmed that the strains were in RFLP group 28, which contains the insect-transmitted SFR strain of race 2 (moko disease) from Venezuela (Akiew and Hyde 1992; Cook et al. 1989). Other strains from *Heliconia* were in race 1 and not pathogenic to *Musa* spp. (Akiew and Hyde 1992). *Heliconia* strains pathogenic to triploid banana are present in Hawaii (Ferreira et al. 1991), and bacterial wilt of banana (bugtok disease) has been reported from the Philippines (Buddenhagen 1986). Moko disease caused by *P. solanacearum* race 2 occurs in cultivated banana only in Latin America, but if introduced to Asia and the Pacific, this insect-transmitted disease could spread to cultivated and wild banana species. To assess the potential risk of introducing moko disease on symptomless *Heliconia* cuttings, further procedures were developed for detection and identification of race 1 and race 2 strains of *P. solanacearum* strains from *Heliconia* using monoclonal antibodies (mAbs), biochemical tests, and genetic probes.

Materials and Methods

Bacterial strains

One hundred and two strains of *P. solanacearum* representing races 1, 2, and 3 from Central America, Asia, and Hawaii were collected and restreaked onto tetrazolium chloride (TZC) medium (Kelman 1954) to check for purity. A survey of 20 Hawaiian farms for

bacterial wilt of *Heliconia* included isolations from 842 rhizomes from 417 clones introduced to Kauai from Ecuador, Venezuela, and St Lucia. Twelve strains were isolated from *Heliconia* rhizomes on Oahu, Maui, and Hawaii; 11 were from *H. psittacorum* and 1 from *H. rostrata*. An additional strain was isolated from ornamental banana (*Musa* sp.)

Pathogenicity tests

Initial pathogenicity tests were performed by wounding the rhizome of *Heliconia* or pseudostem of banana with a sharp metal rod (1-mm diameter) and injecting ca. 1×10^8 colony forming units (cfu) into the wounded tissue. Plants were incubated in the greenhouse, and symptoms of wilt, chlorosis, or necrosis were read daily for 21 days. Pathogenicity tests were repeated on tissue-cultured banana cv. Williams. Plants were inoculated 2 months after deflasking by injecting approxiametly 1 mL of inoculum into the pseudostem; plants were incubated at 26 to 28°C under a 12 hour day–night cycle using Gro-Lux illumination (60 $\mu Em^2/s$, as measured with Li C or solar monitor using a quantum flux sensor) and checked for symptoms of bacterial wilt over 21 days. Tomato cv. Healani and pepper (*Capsicum annum* cv. Keystone) were inoculated ca. 21 days after germination by exposing roots to inoculum, transplanting into a potting mix consisting of fine peat and silica sand. Symptoms of wilt were observed 4–8 days after inoculation.

Biochemical tests

Fourteen strains from *Heliconia*, banana, tomato and potato were characterised by enzymatic reactions and carbon source utilisation using API® rapid NFT strips. Oxidation of 95 substrates was tested on microplates using the Biolog MicroStation™ System, Version 3.00 (Biolog, Inc. Hayward, CA). Oxidation of mannitol, sorbitol, lactose, maltose and cellobiose was recorded separately to give a tentative indication of biovar (Hayward 1964).

Antibody production

Monoclonal antibodies were produced for banana and *Heliconia* strains using methods previously described (Alvarez et al. 1985). Mice were immunised with a mixture of bacterial cells of race 1 (strains A3380, A3464, and A3467) or individually with strain A3380, A3294 (race 1), A3381 (race 2, banana), A3908 (race 2, *Heliconia*). After seven separate fusions, supernatants from hybridoma clones were tested with 75 strains in races 1, 2, and 3 and with 73 strains from 5 pathovars of *P. syringae*, 10 other *Pseudomonas* sp., and 24 strains of 4 other genera (Alvarez et al. 1985; Benedict et al. 1989).

Restriction fragment length polymorphism analysis.

A collection of 14 strains composed of representatives of each race was analysed by RFLP analysis using cosmids containing fragments from a race 2 isolate as probes.

DNA was isolated from *P. solanacearum* race 2 strain 3908 isolated from *Heliconia*. Bacteria were grown in a litre of low salt Luria broth, washed with PBS, suspended in 50 mL of 50 mM glucose, 10 mM EDTA, 25 mM tris (pH 8.0) and lysed by the addition of 1 mg/mL lysozyme. After 1 hour at 0°C, 10 mL of 50 mM tris, 20 mM EDTA (pH 7.5), 200 µg/mL proteinase K and 1.8 mL of Sarkosyl was added. After 1 hour at 50°C the lysate was centrifuged at 49500 g for 1 hour. CsCl was added to the supernatant (8.6 g/10 mL). After the CsCl was dissolved, ethidium bromide (1 mg/10 mL) was added and the extract was centrifuged in a Beckman type 70.1 rotor for 16 hours at 55000 rpm followed by 1 hour at 40000 rpm. The DNA was recovered and dialysed exhaustively against 10 mM tris, 0.5 mM EDTA (pH 7.5).

The DNA was partially digested with *Sau*3A and size fractionated on NaCl gradients. Gradient fractions containing DNA from 35 to 45 kb in size were pooled and ligated into SuperCos 1 (Stratagene, La Jolla, CA), packaged and propagated on *E. coli* strain NM554 using procedures recommended by the manufacturer. Individual colonies were isolated and cosmid DNA was prepared from mini-lysates as described by the manufacturer (Stratagene). Cosmid DNA was labeled by 'nick translation' using the Bethesda Research Laboratories Nick Translation Kit and a protocol supplied by the manufacturer.

For RFLP analysis, DNA was extracted from 100 mL cultures grown for 48 hours at room temperature. Cells were collected by centrifugation, washed in 100 mL PBS and suspended in 15 mL of 50 mM glucose, 10 mM EDTA, 20 mM tris (pH 8.0) and 100 mg lysozyme. After 30–60 minutes at 0°C, 0.2 mL 2-mercaptoethanol, 50 mg proteinase K and 1 mL of 35% Sarkosyl were added and the extract was incubated for 1 hour at 65°C. The extract was made 0.7 M in NaCl and 8.1 mL of 1% CTAB in 0.7 M NaCl were added. After 10 minutes at 65°C an equal volume of chloroform and isoamyl alcohol was added. The aqueous phase was recovered after centrifugation and re-extracted with phenol, chloroform and isoamyl alcohol. The aqueous phase was recovered and the nucleic acids precipitated by the addition of 0.6 volume of isopropanol. The nucleic acids were dissolved in 10 mM tris, 0.5 mM EDTA and the RNA was digested with RNAse A (200 µg/mL) at 37°C for 1 hour. The digest was extracted once with phenol and

chloroform and once with chloroform. The DNA was recovered by precipitation with 2.5 volumes of ethanol.

Genomic DNAs were digested with either *Bam*HI or *Eco*RI using conditions recommended by the manufacturer (Promega). Digests (500 ng each) were separated by electrophoresis on 0.8% agarose gels. DNA was transferred to nylon membranes by vacuum blotting and crosslinked by UV light. Hybridisation to 'nick translated' cosmids was done at 65°C in 6 × SSPE containing 2 × Denhardt's solution, 1% SDS and 50 µg/mL denatured salmon sperm DNA for approximately 18 hours. Filters were washed four times in 2 × SSC containing 1% SDS at 65°C for at least 30 minutes each wash. RFLP fragments were visualised by autoradiography for 24–48 hours at –80°C.

RFLP Data Analysis

Each strain was scored for the presence or absence of a specific restriction fragment. Fragment data were converted to similarity coefficients and subjected to cluster analysis. Coefficients of similarity (F) were calculated using the formula: $F = 2n_{xy}/(n_x + n_y)$, where nx and ny are the total number of restriction fragments observed in strains X and Y, respectively, and n_{xy} is the number of fragments shared by X and Y (Nei and Li 1979; Hartung and Civerolo 1989). Cluster analysis was performed by the average taxonomic distance method of the NTSYS-pc program (Exter Publishing, Ltd, Setauket, NY).

Results

Pathogenicity tests

Of 13 strains recovered from *Heliconia* and *Musa* spp. from islands of Oahu, Maui, and Hawaii following a survey of 842 plants, 7 strains caused wilt of both banana and *Heliconia*, but four of these also caused wilt of tomato (Table 1). Yellowing and leaf curl were visible on banana within 2 weeks and later developed into wilt. Veins darkened at the point of inoculation and proceeded upwards into the pseudostem. Plants died within 21–28 days after inoculation. Controls (injections with sterile saline or suspensions of *P. cicchori*, *E. herbicola*, and *Xanthomonas campestris*) developed no symptoms. Five *Heliconia* strains caused wilt on Heliconia and tomato, and one strain affected only *Heliconia*. Tomato and *Heliconia* plants wilted within 4 and 21 days, respectively. None of the strains recovered from *Heliconia* grown on Kauai was pathogenic.

Table 1. Pathogenicity tests of *Pseudomonas solanacearum* on tomato, banana, and *Heliconia*.

Lab. No.	Aquisition No.	Host	Ability to cause wilt			Race	Origin	Source[a]

[a]Cultures were received from (1) S. Ferreira, University of Hawaii; (2) D. Cook, University of Wisconsin ; and (3) M. Natural, University of the Philippines, Los Baños.

[b]Tentatively identified as race 2, although race 2 should not give positive reactions on tomato.

[c]This reaction is typical of D strains from *Heliconia* reported by Buddenhagen, 1965.

Biochemical tests

Of 14 strains tested with the NFT analytical tabs, all but two (A3912 and A3455) had the general characteristics of *P. solanacearum*. Strains varied with respect to growth on seven carbon sources, but were consistent in being positive for nitrate reduction and glucose utilisation, and negative for tryptophanase, arginine dihydrolase, urease, esculin hydrolysis, gelatinase, and hydrolysis of p-nitro-phenyl-beta-galactopyranoside (PNPG). Strains A3912 and A3455 were negative for nitrate reduction but positive for PNPG.

Based on differential oxidation of 95 carbon sources in the Biolog system, *P. solanacearum* was the closest match for 8 of the 14 strains tested. Strains from *Heliconia* and tomato failed to oxidise carbon sources that characterise biovars of *P. solanacearum*, and thus were similar to biovar 1; however, strains from potato classified as biovar 2 (Cook et al. 1989; Hayward 1964; Hayward 1991) failed to oxidise maltose, lactose and cellobiose in these assays.

Monoclonal antibodies

Antibody-producing hybridoma clones of selected specificities are shown in Table 2. Two distinct types of mAbs were selected: those that reacted with nearly all *P. solanacearum* strains and those that subgrouped the *P. solanacearum* strains. MAbs Ps1a and Ps1b, produced by hybridomas selected from separate fusions following immunisation with strains from peanut or banana, showed identical specificities. They reacted with 73 of 75 strains tested but did not react with two avirulent strains that formed butyrous, dark red colonies on TZC medium. MAb Ps1a was useful for preliminary identification of *P. solanacearum* in diseased plant samples. When tested against 9 banana strains from the Philippines, it reacted with all but two strains, which later were found to be nonpathogenic on banana and failed to give a hypersensitivity response (HR) on tobacco. Other mAbs were useful for subgrouping *P. solanacearum*, but reactivity patterns of race 2 strains overlapped with those of tomato and potato strains (Table 3).

RFLP analysis

Blots of restriction digests of DNA from 14 strains probed with cPs3908-1 and cPs3908-2 are shown in Figures 1 and 2. Strains from *Heliconia* race 1 showed similar patterns by restriction analysis and were distinct from race 2 strains. DNAs from the two strains, A3912 and A3455, which were atypical in their inability to reduce nitrate (Hayward et al. 1990), and failed to hybridise or hybridised weakly with these probes. A dendrogram based on the combined RFLP data from cPs3908-1 and cPs3908-2 shows the relationships between the strains isolated from heliconia, banana, tomato, and potato (Fig. 3.)

Discussion

Based on pathogenicity to banana and *Heliconia* only three of the *P. solanacearum* strains isolated from *Heliconia* grown on the islands of Oahu, Maui, and Hawaii were clearly race 2 (Buddenhagen and Kelman 1964). Intermediate forms pathogenic on banana, *Heliconia*, and tomato were tentatively classified as race 2, and may represent the transitional forms

described by Buddenhagen (1965). Strains pathogenic only to *Heliconia* and tomato, classified here as race 1, have been encountered previously on *Heliconia* spp. from Oahu and Hawaii, but have not yet been encountered on Kauai (Ferreira et al. 1991).

With both biochemical and mAb analyses the *Heliconia* strains had general characteristics of *P. solanacearum* but neither of these methods delineated race 2 strains from other races. However, mAb Ps-1a is very useful for species identification directly from plant samples and was negative for avirulent mutants of *P. solanacearum*.

Data from RFLP analysis distinguished *Heliconia* strains from other *P. solanacearum* strains and formed two clusters consisting of race 1 and race 2 strains, respectively. The *Heliconia* strains showed less than

50% homology of RFLP fragments with the Costa Rican race 2 strain reported in RFLP group 24 (Cook et al. 1989). The bugtok strains isolated from banana in the Philippines appear to be distinct both from the Hawaiian *Heliconia* strains and the race 2 strain from Costa Rica. On blots from two additional probes, cPs3908-3 and cPs3908-4, however, banding patterns between the Costa Rican strain and the two Philippine strains were nearly identical (data not shown).

Although only tentative conclusions can be made from these preliminary results, the RFLP groupings show geographical and biological significance. Pending further analysis, we will focus on developing DNA probes specific for the *Heliconia* strains that differentiate them from other race 2 strains of *P. solanacearum*.

Diversity of *Pseudomonas solanacearum* in Peru and Brazil

E.R. French*, P. Aley*, E. Torres† and U. Nydegger*

Abstract

Isolates of *P. solanacearum* in the International Potato Center (CIP) collection have been classified into biovars. Those from Peru are: biovar 1/race 1 from the Amazon lowlands and Northern highlands; biovar 1/race 2-strain A and biovar 3/race 1 from the Amazon lowlands; biovar 2-A/race 3 from the Andean highlands and cool coastal desert; and biovar 2-T/tropical lowland variant found in San Ramon, Junin Department (1150 m elevation) and Yurimaguas, Loreto Deptartment (170 m). Strains of biovar 1/race 1 and biovar 2-T have been found together in the same fields and even in the same plant at Yurimaguas. These differed consistently in size on Kelman's medium (average diameters 1.0–1.5 mm and 1.8–2.5 mm, respectively) and they have distinctive formazan pigment patterns. Brazilian isolates are: biovar 1/race 1 and biovar1/race 2 in the warmer ecoregions; biovar 2-A/race 3 in the south; biovar 2-T in central Brazil; and biovar 3/race 1 in central and northern Brazil. Biovar 2-T, that is metabolically more active than biovar 2-A, was pathogenic on potato, tomato and eggplant in field tests in San Ramon, but not on pepper and tobacco; whereas biovar 2-A was only pathogenic on potato at Umari, Huánuco Department (2,400 m). Biovar 2-T was less virulent on clones developed for resistance to bacterial wilt, 7 of 32 being highly resistant at tropical San Ramon, whereas only four were resistant to biovar 2-A in the highlands at Umari. However, only one of the clones was commonly resistant at both locations, indicating a marked differential host–pathogen interaction. Biovar 2-T was not present among the numerous biovar 2 isolates from other potato-producing countries in other continents.

BACTERIAL wilt caused by *Pseudomonas solanacearum* E.F. Smith was not noticed in Peru until 1966 when Moko disease of plantains and bananas, and wilt of tomato (*Lycopersicon esculentum* L.) were detected along the Amazon river (French and Sequeira 1970), and a year later wilt of potato (*Solanum tuberosum* L) was found in the highlands (Herrera and French 1970). Attempts to find native hosts by observing wilt symptoms of highland vegetation, native jungle species or among jungle crops and weeds were unproductive, though some transplanted wild jungle plants were shown to maintain or increase the inoculum potential (French et al. 1981).

The Amazon basin, which is located primarily in Brazil and Peru, was recognised as an area of greater diversity for *P. solanacearum* (French 1979). A biovar 2 strain that was not the low-temperature potato strain synonymous to race 3, was found in the lowlands of Peru in valleys of tributaries of the Amazon river. Its host range seemed greater, since eggplant (*Solanum melongena* L.) wilted under field conditions where it was found. Since this strain is indigenous in tropical rain forest, it was postulated that race 3 may have diverged from this tropical strain when potatoes were planted in these lowlands, and healthy looking tubers from wilted plants were carried with latent infection to the highlands and used as seed. Over considerable time, a new strain adapted to the potato, which is usually grown in cool climates, may have evolved (French 1986; Martin et al. 1981; Torres 1983). The readiness with which *P. solanacearum* is disseminated as latent infection in tubers has been shown (Ciampi et al. 1980; French and Nydegger 1990).

At The International Potato Center (CIP) we established collaboration with Drs A.C. Hayward and L. Sequeira to further define these and other strain differences. A collection of 327 isolates of *P. solanacearum* was assembled and detailed physiological and RFLP

*International Potato Center (CIP), Apartado 5969, Lima 100, Peru

†Universidad Nacional de Huánuco, Huánuco, Peru

studies conducted. These led to findings which included confirmation of the existence of two phenotypes of biovar 2. The tropical lowland phenotype was designated biovar 2-T (CIP 1991; Hayward et al. 1990a, 1990b, 1992).

The presence of more than one bacterial strain in a given plant was recognised because of different colony size and formazan pigmentation patterns in an agar streak, when both a biovar 1 and a biovar 2 were present in a plant from the highland site of Huambos, Cajamarca. Similarly biovars 1 and 2 were isolated from one plant from the Yurimaguas jungle site (French and Nydegger 1987).

Numerous reports confirm that biovar 2/race 3, which has the greatest distribution in association with the potato, primarily in the cool tropical highlands and cooler latitudes, has a lower optimum temperature for growth and causes infection at lower temperatures than other strains (French 1986). Studies of the optimum temperature for growth of the Peruvian lowland strains of biovar 1 and 2 and isolates of biovars 1 and 2 from cool temperature locations showed no significant differences between them (Nydegger and French 1984). An explanation for the ability of race 3 to cause wilt at cool temperatures, other than a lower optimum temperature for growth, may be its greater aggressiveness or pathogenicity. Gutarra (1980) found that five strains of biovar 2 were on average more pathogenic than two strains of biovar 1, whilst Martin et al. (1982) tested six Peruvian strains, the two biovar 2 being more pathogenic than the four biovar 1. Ciampi et al. (1981) determined that the variety Molinera (resistant to wilt) was not affected by a race 1 (biovar 1) strain, whereas a race 3 (biovar 2) strain caused 20% wilt.

To better understand the diversity of *P. solanacearum* in the Brazilian and Peruvian tropical belt of South America, and especially the variation within biovar 2/race 3 that (along with biovar 1), causes bacterial wilt of potato from the cold highlands to the hot tropical lowlands, information in the CIP *P. solanacearum* collection listing (gathered in part by the authors) was used. Research was conducted on host susceptibility, latency in potato tubers, and the optimum temperature for growth of strains of the bacterium.

Materials and Methods

The accession list of the CIP *P. solanacearum* isolate collection was amplified to show biovar 2 isolates classified as biovar 2-T, and the remaining biovar 2 strains tested were designated biovar 2-A (for Andean). The frequency of presence in the collection of biovars collected within Peru and Brazil was plotted on a map, adding information about the host except when it was potato. The names of Departments of Peru and States of Brazil, which included data, were added.

To determine if five solanaceous hosts commonly grown in other parts of Peru were susceptible to the strain of *P. solanacearum* found when potatoes were introduced to jungle soils, susceptibility tests were conducted in a field heavily infested with biovar 2-T during November and December, the time of heavy summer rains. True seed of hot pepper (*Capsicum baccatum* var. Escabeche), tomato (var. Marglobe), tobacco (*Nicotiana tabacum* L. var. Sansum), eggplant (var. Black Beauty) and potato (var. Atzimba) were germinated in trays containing peat and sand (2:1). These were then transplanted when 2–3 cm tall to Jiffy 7 peat blocks and 25 days later planted at La Chincana, San Ramon District (11°03'S, 75°19'W at an altitude of 1150 m above sea level) in a completely randomised block design (CRBD) with four replications. Two-row plots 6 m long containing 20 plants of a given plant species were planted with between row spacings of 90 cm and within-row spacings of 50 cm. Wilt symptoms were recorded three times at intervals of 15 days. Samples of wilting plants were taken from each plot, to determine the possible variations in strains. The same species of plants were planted at the highland site of Umari, Huanuco (2400 m above sea level) but in continuous rows of each species in sequence, in a field that had been maintained as a wilt nursery.

To determine the resistance performance of several clones bred for resistance to *P. solanacearum* with genes derived from *Solanum phureja* (Torres 1983), a selection of 32 was planted at both La Chincana, Junin Department (1150 m above sea level) where biovar 2-T was consistently isolated, and at Umari, Huanuco Department (9°55'S, 76°14'W, 2400 m above sea level) where biovar 2-A was the only strain present. The pedigrees of the 11 clones that grew well in both environments and were of greater interest, and of the susceptible and resistant checks, are shown in Table 1. The tests were planted twice during the year-end rainy seasons with a CRBD design with three replications of five plants in one row, planted with a between-row spacing of 100 cm and a within-row spacing of 40 cm.

To observe colony characteristics, two isolates of each biovar strain were streaked on Kelman's medium, incubated at 30°C for 48 hours, and colonies viewed in inverted plates with a stereoscopic dissecting microscope with oblique reflected light. Twenty well-separated colonies on five plates per isolate were measured and formazan pigmentation characteristics were recorded.

The optimum temperature for growth was determined in liquid culture (Kelman's medium without agar or TZC) in an oscillating temperature gradient incubator with a temperature range of 25–42°C with

intervals of 0.5°C between each pair of tubes. Tests were repeated four times with two isolates simultaneously. Initial concentration was 1×10^7 cfu/mL. Readings were made by optical density (OD) at 600 nm in a spectrophotometer, at hourly intervals for 8 hours, until the temperature at which growth was fastest at an absorbance of OD 0.5 or more was reached. The eight isolates tested were: two biovar 2-A; two biovar 1 from higher, cooler elevations; two biovar 1 from a low, hot elevation; and two biovar-2-T from the same low elevation (Table 3).

To determine the potential of isolates of the different strains to produce wilt disease and latent infection in potato tubers, plants of Ticahuasi variety were grown in 15 cm diameter clay pots containing about 1 kg disinfested soil mix (2 soil:1 sand:1 moss). Inoculation was done by pouring into the soil mix 50 mL of a suspension of 1×10^8 cfu/mL for a given isolate. Isolates used were: biovar 1, 015 and 077; biovar 2-A, 017 and 102; and biovar 2-T, 107 and 142 (Table 3). Inoculation treatments were 42 and 70 days after planting and they were harvested 54 and 40 days later, respectively. Two greenhouse temperature treatments were 17/26.5 and 26/30.5°C night/day. Percent wilt was determined 10 days before harvest. Tubers with symptoms at harvest were discarded and the remaining healthy appearing tubers were stored at 27–32°C for 42 days, at which time symptoms were recorded either as externally visible or by exudation of the vascular system of halved tubers. Symptomless tubers were assayed by aseptically removing two portions of tissue per tuber of about 0.5 × 0.5 × 2.0 cm, that included the vascular system, and each was placed in a test tube containing 5 mL of sterile water for 15 minutes. Streaking on Kelman's medium followed and incubation for 48 hours at 30°C.

Results

There were 98 isolates from Peru in the collection, most of them contributed by CIP scientists, and 36 from Brazil contributed by colleagues there. The geographical origin of these is shown in Figure 1. In the highlands (above 1500 m above sea level) of the Peruvian Departments of Amazonas, Ancash, Cajamarca, Huanuco, La Libertad, Junin and Piura, as well as the cool coastal Lima, there were eight biovar 1 and 52 biovar 2-A strains, all isolated from potato. In the lowlands (below 1500 m above sea level) of the Peruvian Departments of Loreto and Junin, 32 isolates of biovar 1 included 26 isolated from potato, 2 from tomato and 4 from plantain; 5 biovar 2-A isolates were from potato; 16 biovar 2-T included 13 from potato, 2 from eggplant and 1 from tomato; a single biovar 3 was from tomato (another lowland tomato isolate was a biovar 1 from a lowland jungle site in Huánuco, as shown in Fig. 1).

Fig. 1. Geographical distribution of biovars 1, 2-A, 2-T and 3 of *Pseudomonas solanacearum* from Peru and Brazil, that are present in CIP's collection.

All isolates from Brazil were from below 1500 m above sea level, and all were from the southeast except for a tomato isolate of biovar 3 in Amazonas State. A similar isolate was from São Paulo State. Another 34 isolates in the southeastern states of Goias (and Federal District of Brasilia), Minas Gerais, Rio de Janeiro, Sao Paulo and Santa Catarina were: 14 biovar 1 (12 potato, 1 tomato and 1 *Ageratum conyzoides* L.); 11 biovar 2-A from potato; and 9 biovar 2-T (7 potato, 1 *Solanum americanum* Mill. and 1 *S. sysymbrifolium* Lam.). Biovars 1 and 2 have, in addition, been reported in Rio Grande do Sul and biovar 2 in Espiritu Santo, and several weed hosts reported without specifying biovar or race (Lopes and Reifschneider 1983; Robbs et al. 1974).

At the La Chincana lowland site, symptoms appeared first in potato and eggplant, with 2.5% wilt incidence on average for each at 15 days. First symptoms on tomato were recorded at 30 days. There were no symptoms in tobacco or pepper at 45 days. The average per plot at 45 days was: potato, 74%; eggplant, 39%; and tomato, 16%. *P. solanacearum* was isolated repeatedly from each plot with a susceptible host. All isolates were characteristic of biovar 2-T in colony size and formazan pigmentation; representative samples were accessed to the collection and were classified by physiological tests as biovar 2-T. At the Umari highland site only potatoes developed wilt, and all isolations were biovar 2-A. These records on biovar strains appear in the Huánuco and Junin listings in Figure 1.

Percentage wilt and tuber infection (Table 2) data for the potato clones bred for resistance to wilt and tested at two sites are averages for two seasons. Only BR 63.76 and its sister clone Molinera (BR 63.65 resistant check) were resistant at both locations. MS 35.9 and the susceptible check were susceptible at both locations. Clones BR 63.15 and MB 6.42 were moderately resistant at La Chincana and resistant at Umari. Clones MS 84.5, MB 5.24, and Cruza 148 were resistant at La Chincana and susceptible at Umari. The remaining four were resistant at La Chincana and moderately resistant at Umari. Tuber symptoms at harvest were present in Umari and absent at La Chincana. Symptoms after storage of 10 symptomless tubers per plot for 30 days at 28±3°C occurred for both sites.

In the study of colony characteristics it was found that biovar 1 isolates had diameters ranging from 1.0–1.5 mm; biovar 2-A from 1.8–2.3 mm; and biovar 2-T from 2.4–2.5 mm. Formazan pigmentation was highly characteristic for biovar 2-T in which dark helicoidal red streaks were superimposed on a diffuse reddish central pigmentation. Differences between biovar 1 and biovar 2-A colonies were apparent but not so easily defined. In one instance, during the process of isolation of the causal agent from a wilted plant collected at Yurimaguas, two colony types were easily distinguished in the streaks on agar plates resulting in isolates 177 (biovar 2-T) and 178 (biovar 1). Similar situations allowed the isolation of pairs of biovar 1 and biovar 2-A isolates (202–203 at Huambos, Cajamarca; also 300–301, 302–303, 304–305, 306–307 at San Ramon, Junin). Biovar 2-T was also isolated, singly, at this last site, and readily diagnosed as such.

Results of studies of optimum temperature for growth of isolates are shown in Table 3 with their respective temperature optima and hours taken to reach O.D. 0.5 at that optimum temperature. Results were consistent between repetitions. The isolates from the three high elevation sites took longer, and had the lowest optimum temperature for growth, but these optima were similar to some of those for lowland strains.

Percent wilt and latent infection resulting from the inoculation of Ticahuasi potato plants in two temperature regimes is shown in Table 4. Biovar 2-A isolates were more pathogenic than the others at both temperature regimes, whilst biovar 1 and biovar 2-T were similar at the higher temperature and biovar 1 more pathogenic than biovar 2-T at the cooler temperature. Latent infection differed with some strains according to the date of inoculation and temperature. On average,

Table 3. Optimum temperatures for growth of isolates of different biovars (biovar) of *Pseudomonas solanacearum* isolated from potato in Peru, and number of hours taken to reach optical density (OD) 0.5.

Biovar	Isolate no.	Location	Altitude (m above sea level)	Optimum temperature°C	Hours to OD 0.5

	70	78.0	18.4	92.0	27.3	68.0	44.0
Average		70.2	12.3	96.0	13.7	74.0	25.2
General average		65.2	8.3	85.0	18.6	57.5	17.4

[a]Days inoculated, 42 and 70. Plants were harvested 54 and 40 days later, respectively.
[b]Tubers with symptoms were discarded at harvest, others were stored at 27–32°C for 42 days after which symptoms were recorded as latent.

biovar 1 resulted in less latent infection, whereas it was greater and similar for biovars 2-A and 2-T. At the lower temperature, however, biovar 2-A produced more than double the latently infected tubers than biovar 2-T.

Discussion

Only Peruvian isolates originated above 1500 m elevation in the highlands (since none of the Brazilian isolates were from regions with highlands), where biovar 2-A/race 3 predominated and was isolated only from potato. A low frequency of biovar 1/race 1 isolates came from the lower reaches of these Andean Highlands, having been isolated from potato and tomato, whereas there were numerous isolates of biovar 1 from potato and a few from tomato for the lowlands. A few isolates of biovar 2-A of recent isolation were from one field in the lowlands at San Ramon.

In Brazil, biovar 2-A also originated only from potato, but rather than coming from high elevations it was from more southerly higher latitudes. Biovar 1, on the other hand, originated in lower latitudes, from potato, tomato and *A. conyzoides*. Biovar 1 isolates outnumbered those of biovar 2-A.

Biovar 2-T isolates were from the lowlands and primarily from potato in lands recently placed in cultivation in both Peru and Brazil, but also from eggplant and tomato in Peru and two solanaceous weeds in Brazil.

Apart from the biovar 1/race 1 isolates mentioned above, four biovar 1 isolates of race 2-Amazon strain from Peru were representatives of the epidemic reported as moving west up the Amazon river basin from Brazil and Colombia into Peru (French and Sequeira 1970). In addition to biovars 1, 2-A, and 2-T, isolates of biovar 3/race 1 isolated from tomato were from the Amazon basin in both Brazil and Peru and also São Paulo State in southern Brazil.

The distribution of strains is consistent with the proposition that biovar 2-A/race 3 is a strain highly specialised on potato, and that it has spread primarily in latently infected tubers. The only case of infection in the lowlands of Peru resulted after potatoes had been grown for many years utilising highland seed, which could have been at times infected latently with *P. solanacearum*. Its presence in southern Brazil on potatoes only, as is also the case in numerous potato-growing countries at much colder latitudes, is further circumstantial evidence that this is a strain that has spread worldwide from one common origin, probably the Andean highlands, and likely through Europe from where potatoes were redistributed to most potato-growing countries worldwide (French 1979).

Nineteen isolates of biovar 2-T were from the tropical rain-forest lowlands of eastern Peru and in or close to the 'cerrado' brushland of eastern Brazil, whilst the remaining 111 biovar 2 isolates from locations worldwide, were biovar 2-A. Should future surveys demonstrate that these are the margins of a vast region that may extend even further north and south, in which biovar 2-T is indigenous, this would suggest that the variability of biovar 2 is greatest in South America, and that both biovar 2-T and 2-A originated in this region, with the more specialised 2-A evolving from 2-T (French 1979; Hayward et al. 1992; Martin et al. 1981).

The testing of five solanaceous crops in land infested with only biovar 2-T at La Chincana, as demonstrated with the isolations made, further supports the above conclusions since under field conditions eggplant, tomato and potato developed wilt. Biovar 2-A generally causes wilt of potato only and rarely tomato (French 1986). It would be interesting to test these crops in land infested with biovar 2-T in the 'cerrado' of Brazil, where another strain named 'campo-bi' causes 100% wilt when virgin land is planted to potatoes, and none if planted a second time;

but if beans are planted first, they do not wilt, whereas a subsequent crop of potatoes does (Lopes and Reifschneider 1983).

The testing, in the La Chincana lowland site infested with biovar 2-T and the Umari highland site with biovar 2-A of potato clones bred for resistance to bacterial wilt, resulted in less wilt and fewer clones being susceptible to biovar 2-T in spite of higher temperatures favourable for disease. This differential pathogen–host interaction between the two sites needs confirmation under identical environmental conditions. Biovar 2-A resulted in more than double the average wilt incidence under less favourable temperature conditions than that caused by biovar 2-T (however, the inoculum potential was slightly higher as suggested by the percentage wilt in the resistant check, 18 vs. 14%). In the greenhouse inoculations, biovar 2-A isolates of cool climate origin were more pathogenic than both biovar 2-T and biovar 1 isolates that originated in warmer locations. These results lend further support to the proposition that it is due to greater aggressiveness, especially expressed at lower temperatures, that biovar 2-A/race 3 strains are pathogenic under cool climate conditions atypical for *P. solanacearum*. (Ciampi et al. 1981; French 1979; Gutarra 1980; Martin et al. 1982).

The studies of optimum temperature for growth of isolates from different agroecologies, on the other hand, did not show clear differences between the three strains. It should not be expected, *a priori*, that strains indigenous in the same ecological niche (biovar 1 and biovar 2-T from Yurimaguas) would differ, but even the optimum temperatures for growth of biovars from the high Andes and low Amazon Basin differed very little in this study.

Latent tuber infection resulted in the field test with biovar 2-T, but no symptoms at harvest; biovar 2-A produced symptoms at harvest in spite of a cooler climate, and also latent infection. Average tuber infection was greater with biovar 2-A. Both factors again suggest, a greater aggressiveness of biovar 2-A. In greenhouse tests, biovar 2-A was also more pathogenic at both temperature regimes than biovar 2-T (and biovar 1) but latent infection resulted from both, and was even greater for biovar 2-T at the higher-temperature regime more akin to tropical climates where it occurs. Biovar 2-T was less aggressive, resulting in little or no external symptoms. Thus, tubers harvested under the tropical conditions where this strain occurs could be carried to higher elevations where seed production is preferred. Such a happening centuries or millenia ago may have been the beginning of a process of evolution of the more specialised biovar 2-A. Latent infection by biovar 1 was lower, which may indicate it had less probability of evolving into a highland strain (however, isolate 042 originated at 3350 m above sea level, an altitude similar to the highest elevations recorded for biovar 2-A).

Colony phenotype (size, formazan pigmentation) was shown to be a useful tool to distinguish mixtures of isolates during the isolation from plants with dual infections. Thus, distinctions were recorded as having been made between biovar 1 and biovar 2-A, and biovar 1 and biovar 2-T. For one field at San Ramon the distinction was made between biovars 1, 2-A and 2-T (the first two in dual infections, the last singly). Colony differences are thus useful in the separation of different strains for given locations, but these differences may not hold true over a greater geographical range.

It can be concluded that the Amazon basin and adjacent lands (in Brazil, Peru and possibly neighbouring countries) are a region of greater diversity for *P. solanacearum*, it being the only region in the world where the lowland variant biovar 2-T occurs. Further, there is evidence pointing to biovar 2-A/race 3 having evolved from biovar 2-T. If so, the worldwide distribution of biovar 2-A/race 3 could be explained only as having resulted from the transport of latently infected tubers from the Andean region of the New World to Europe, and subsequently in the traditional seed trade routes (or even by exchange between agricultural researchers) to the large number of countries on all inhabited continents that now have it, including southern Brazil.

Pathogenicity of the New Phenotypes of *Pseudomonas solanacearum* from Peru

J.E. Marín* and H.M. El-Nashaar†

Abstract

Pathogenicity of bacterial strains of phenotype A (063, 162 and 299) and phenotype B (050, 204 and 431) representing biovar 2 of *Pseudomonas solanacearum* was determined using *Solanum tuberosum* cv. Ticahuasi, *Lycopersicon esculentum* cv. Marglobe, *Nicotiana tabacum* cv. Samsun, *S. melongena* cv. Black Beauty, *S. nigrum*, *Cyphomandra betacea* and *Datura stramonium*. Isolates from biovar 1 (003 and 303) and biovar 3 (072) were used as tester standards. Ten 40–50 day old seedlings were inoculated with *P. solanacearum* using a Hamilton microsyringe delivering 10 µL per site/plant of a suspension containing 1×10^8 cfu/mL into the stem. For potato, cuttings of similar age were used. Plants were evaluated after 5 days of incubation at 26–30°C and every 5 days thereafter for 20 days. Except those isolates of phenotype B which did not cause wilt of tobacco, all strains induced some host response. The reaction of *N. tabacum* and *S. nigrum* to inoculation with strains of biovars 1, 2 and 3 was differential. This demonstrated that phenotype A has a much wider host range than phenotype B. It is evident that phenotype A behaves similarly to isolates of race 1, due to its ability to induce a hypersensitive reaction and to cause wilt in tobacco. Phenotype B is, therefore, less related to phenotype A. Added evidence for the great diversity of *P. solanacearum* and the existence of a variant(s) of biovar 1, which is closely related to phenotype B, are reported.

BACTERIAL wilt caused by *Pseudomonas solanacearum* E.F. Smith affects many crops in tropical and subtropical regions of the world. The pathogen has a wide host range and survives in soil for extended periods (Buddenhagen and Kelman 1964; Hayward 1991; Kelman 1953). In Peru, potato and banana are the two crops most often affected by the disease (French and Sequeira 1968, 1970; French and Nydegger 1990).

Strains of *P. solanacearum* vary greatly in biochemical activities, host range and ability to cause disease. Various classification schemes have been proposed. Buddenhagen et al. (1962), classified a large number of isolates into three races: race 1 contains strains that are pathogenic on tobacco, many other solanaceous hosts and other plant species; race 2 strains are primarily pathogenic on plants from the family Musaceae; race 3 strains affect potato and tomato and a limited number of other hosts. Hayward (1964) grouped isolates of *P. solanacearum* into four biovars (biovars 1-4) according to their ability to oxidise disaccharides or utilise hexose alcohols. In a study which included isolates from *Morus alba* from China, He et al. (1983), described a group of isolates that did not fit any of the previously reported races and biovars. They proposed that these isolates belonged to biovar 5 and possibly race 4. Isolates from race 3 correspond to biovar 2, but the reverse is not always the case (Buddenhagen 1986).

In Peru, biovars 1–3 are present (French and Nydegger 1990; Martin et al. 1981). Studies of the variabilities of strains from these biovars are lacking. Recently, Hayward et al. (1990a) determined that there are two phenotypes within biovar 2 that differ in their metabolic activities. Phenotype A which includes isolates that are metabolically more active, was thought not to behave as race 3 and most probably to have a wider host range. Isolates representing phenotype B are less metabolically active, but possibly correspond to race 3. The purpose of this study was to confirm the biochemical characteristics of the Peruvian

isolates of biovar 2; determine the pathogenicity of isolates from phenotypes A and B; and, investigate the race/biovar relationship of the Peruvian strains of biovar 2.

Material and Methods

Strain selection and maintenance

Thirty four *Pseudomonas solanacearum* isolates representing biovar 2 were used for biochemical characterisation. Six strains equally representing phenotypes A and B of biovar 2 were evaluated for study of host range and symptomatology. In addition, strains CIP-003 and CIP-303 (biovar 1) and strain CIP-072 (biovar 3) were used as references. Details concerning the origins of all strains used are shown in Table 1.

The International Potato Center (CIP) maintains one of the largest collections of *P. solanacearum* in the world. Strains are kept in screw-capped tubes containing bacterial suspension in sterilised distilled water (Kelman and Person 1961). Bacterial strains were replated on Kelman medium with 2,3,5- Triphenyltetrazolium Chloride (TZC) (Kelman 1954) for initial verification. Typical colonies after 48 hours of incubation at 28-30°C were transferred onto Kelman medium without TZC. Typical *P. solanacearum* cultures were then transferred into new tubes containing sterilised distilled water (SDW). New tubes were used as the source of bacterial isolates throughout the experiments.

Inoculum preparation

Inocula for pathogenicity tests and biochemical characterisation were prepared from 48 hour cultures on Kelman medium without TZC grown at 28–30°C. Inocula for pathogenicity tests were prepared by suspending bacteria in SDW and adjusting to 1×10^8 cfu/mL using a spectrophotometer (Bausch and Lomb spectronic 20), transmission at $A_{600} = 0.1$. Inoculum was used immediately after preparation.

Biochemical characterisations

Characterisation of all 34 isolates was carried out using tests for oxidase, catalase and hydrolysis of Tween-80 according to Lelliott and Stead (1987), solubility in 3% KOH (Suslow et al. 1982), nitrate reduction (Hayward et al. 1990b) and production of dark brown pigments on Kelman medium without TZC, supplemented with 0.01% l-tyrosine (Hayward 1964).

Determination of biovars and phenotypes was carried out by applying the methods of Hayward (1964) and Hayward et al. (1990a). Pectate gel degradation was tested as described by Hildebrand (1971).

[a]Strains used for pathogenicity.

Pathogenicity tests

Host plants. Plants of *Solanum tuberosum* L. cv. Ticahuasi, *Lycopersicon esculentum* Mill. cv. Marglobe, *Nicotiana tabacum* L. cv. Samsun, *Solanum melongena* L. cv. Black Beauty, were used, together with *Solanum nigrum* L., *Cyphomandra betacea* L. (tree tomato) and *Datura stramonium* L.

Potato plants were obtained by sowing pathogen free tubers in 6-inch pots containing CIP's sterilised soil mix consisting of organic matter:sand:soil (2:1:1). Twenty-five days later, apical cuttings were obtained, allowed to root in sterilised distilled water and were transplanted to 4-inch pots (1-plant per pot) containing the same soil mix. Plants were incubated at ambient screenhouse until inoculation. Two days before inoculation, plants were transferred into the greenhouse where the temperature was 26–32°C and the relative humidity 78–95%.

Plants other than potato were grown from botanical seeds in trays containing sterilised soil mix consisting of organic matter:soil (2:1). Vigorous seedlings were treated in the same fashion as the rooted cuttings of potato plants.

Inoculation. Stems were injected (Winstead and Kelman 1952) using glass microsyringe (Hamilton Co., Reno, Nevada, USA). Ten microlitres of bacterial suspension from each of the nine bacterial strains (Table 1) were delivered into the axil of the second or third leaf from the apical meristem.

Symptomatology and severity. Five genera with 7 species were used for symptomatology and disease severity tests. Each of the 9 strains was injected into 10 plants from each host. Plants were evaluated at 5-day intervals for 20 days after inoculation. Disease severity was recorded on a 1–5 scale: 1= no visible symptoms; 2= 1–25% of the plant is wilting; 3= 26–50% wilt; 4= 51–75% wilt; and 5= more than 75% wilt. Virulence of each strain was rated according to the mean performance of 10 plants from each host 20 days after inoculation: avirulence = 1.0; low virulence = 1.1–2.5 ; medium virulence = 2.6–4.0; and high virulence = 4.1–5.0 (Kelman and Person 1961).

Results

Biochemical characterisations

All 34 strains presented morphological characteristics that were typical of *P. solanacearum* on Kelman medium with TZC. Strains reacted positively for oxidase, catalase, solubility in 3% KOH tests and for reduction of nitrate to nitrite. These results agreed with the reported pattern of this species (Palleroni 1984).

Oxidation of the disaccharides and utilisation of the hexose alcohols permitted verification of each strain to its respective biovar. Additional tests allowed the confirmation of the phenotypes A and B of Hayward et al. (1990a). Results of these tests are shown in Table 2.

Strain CIP-003 (biovar 1) was less metabolically active than strain CIP-303 of the same biovar. The former strain reacted similarly to phenotype B (biovar 2), whereas the latter strain had a metabolic pattern which was similar to phenotype A (biovar 2). Strain CIP-072 (biovar 3) gave positive reaction in all tests realised in this study. In addition, this strain was the most active among all evaluated strains.

Pathogenicity tests

Symptomatology and severity. In general, wilt symptoms varied with time, host plant and strain of *P. solanacearum* (Figs 1A-D and 2A-C). The symptoms that developed on potato and tomato plants initiated on the leaf just below the injection site about 4-5-days after inoculation (DAI). Plants from both hosts wilted rapidly in response to inoculation by any of the isolates. Data for five strains are shown (Figs 1A-B). Eggplant (Fig. 1C) required 8-10 days for symptom development upon inoculation with any of the strains. In tobacco (Fig. 1D) symptoms were developed after 4 and 8 days from inoculation by isolate CIP-303 (biovar 1) and CIP-072 (biovar 3), respectively. Similarly, symptoms were developed 5 and 9 DAI with (CIP-063, CIP-162) and CIP-299 (biovar 2 phenotype A). On the other hand, no symptoms were developed 20 DAI by biovar 2 phenotype B strains. Inoculation with CIP-003 (biovar 1) induced wilt symptoms 10 DAI. Symptoms on *Datura stramonium* (Fig. 2A) were developed at 5 DAI with BV-II phenotype A (CIP-063, CIP-162 and CIP-299) and CIP-303 (biovar 1). Strain CIP-072 (biovar 3) required 8 DAI for development of symptoms. Symptoms were observed at 10 and 13 DAI with strains biovar 2 of phenotype B and CIP-003, respectively. All strains except CIP-063 caused wilt symptoms on *Cyphomandra betacea* (Fig. 2B) plants at 8-9 DAI. Strain CIP-063 induced symptoms at 5-DAI. *Solanum nigrum* plants (Fig. 2C) which were inoculated with strains of biovar 2 phenotype B or CIP-003 (biovar 1) developed symptoms within 6-10 DAI. For the plants that were inoculated with strains of biovar 2 phenotype A, 13-15 days were necessary before symptoms development. Strains CIP-303 (biovar 1) and CIP-072 (biovar 3) did not induce any symptoms during the observation period of this experiment.

Virulence of each of the 9 strains used for pathogenicity tests is presented in Table 3. All strains were highly virulent on tomato, potato, eggplant, tree tomato and *D. stramonium*. Strains of biovar 2 phenotype A and CIP-303 (biovar 1) were highly virulent on tobacco plants, but virulence of CIP-072 (biovar 3) was intermediate. Virulence of CIP-003 (biovar 1) was very low. No virulence was recorded when tobacco was challenged by any of the strains from biovar 2 phenotype B. The latter phenotype B strains and strain CIP-003 (biovar 1) were extremely virulent on *S. nigrum*. Virulence of biovar 2 phenotype A strains was very low on the same host. CIP-303 (biovar 1) and CIP-072 (biovar 3) did not register any

virulence response. *P. solanacearum* was re-isolated from all hosts on which no virulence response was recorded. The recovery of the bacterium from asymptomatic plants was possible at 20 DAI, but the pathogen was confined to tissues near the inoculation site.

Discussion

Biochemical characterisation methods of Hayward (1964) and of Hayward et al. (1990a) successfully distingushed biovars and phenotypes of *P. solanacearum* strains used in this investigation. In addition, among the Peruvian strains a new variant was identified within biovar 1. CIP-003 from potato differed from the San Ramon strain CIP-303 from potato in biochemical activities, colony morphology on Kelman with TZC and in pathogenicity tests, although both strains belonged to biovar 1. Differences in metabolic activities between phenotypes A and B of Hayward et al. (1990a) were complemented by the pathogenic differences reported in this study. Tobacco and *S. nigrum* were the two hosts which represented

differential response among the 9 strains evaluated for pathogenicity. *S. nigrum* might be the model host to study the genetics of *P. solanacearum*-host interactions.

All strains from biovar 2 phenotype A that were isolated from the lowland (relatively high temperature) of the Peruvian jungle, gave the same reactions as CIP-072 (biovar 3) and CIP-303 (biovar 1) strains when cultured on Kelman medium with TZC, evaluated for patterns of biochemical properties and in pathogenicity tests, indicating that strains of biovar 2 phenotype A are closely related to those of biovars 1 and 3. Strains that belonged to the latter two biovars correspond to race 1, whereas strains of biovar 2 are referred to as race 3 of *P. solanacearum* (Hayward 1991). On the other hand, strains of biovar 2 phenotype B reacted similarly to the strain CIP-003 of biovar 1 in all biochemical properties except for utilisation of the three disaccharides which differentiate between the two biovars. These strains were collected from the high altitudes of the Andes, which represent geographical zones of a relatively lower temperature and are certainly agroecologically different from the above mentioned zones of the lowlands.

Phenotypes A and B differed in their metabolic activities (Hayward et al. 1990a), host range (present study), and their abilities to induce a hypersensitive response (HR) in tobacco leaves (Marín 1992; Marín and El-Nashaar, unpublished data). Tobacco host response was the property used by Lozano and Sequeira (1970) to differentiate between races (1-3) of *P. solanacearum*. Strains of biovar 2 phenotype A induced necrosis within 48-72 hours after infiltration of tobacco leaves with the bacterial suspension. This was the typical host response of race 1 strains. The same phenotype caused wilt in tobacco at least 5-9 days after inoculation, which was an added characteristic for race 1 strains. Meanwhile, biovar 2 phenotype B induced chlorosis of the infiltrated area of the leaves. This differed from the response of phenotype A and confirmed the close relationship between race 3 strains and those of phenotype B. Although strain CIP-003 behaved (in pathogenicity and biochemical properties) as a variant of biovar 1, such reactions classify it closely to phenotype B of biovar 2.

We realise that additional data about host reaction to a large group of isolates are needed. At the time this investigation was done, the Peruvian strains employed were the only ones available. Recently, additional strains were collected from Piura. These strains were verified as biovar 1 and are being used in comparative host range studies.

Genomic Fingerprinting and PCR Analysis: Rapid, Sensitive and Inexpensive Means of Differentiating Strains of *Pseudomonas solanacearum*

M. Gillings and P. Fahy*

Abstract

There is a wealth of evidence from physiological, biochemical and ecological studies showing that *Pseudomonas solanacearum* is a heterogeneous species. The complexity of the species must be taken into account by workers in plant health, quarantine, epidemiology and resistance breeding, since the different strains of *P. solanacearum* may have quite different properties and geographic distributions. There is a need for rapid methods of both detecting the bacterium and identifying isolates to infrasubspecific levels. These methods must be easy to perform, suitable for use in developing countries and readily reproducible without recourse to reagents not widely available within the scientific community. A number of DNA-based methods offer the possibility of identifying individual isolates to the level of clonal lines, and yet also fulfil the criteria listed above. Two such methods are analysis of total genomic restriction patterns, and restriction analysis of an amplified fragment of the endopolygalacturonase gene (*peh* A). Both methods readily differentiate isolates, subdividing *P. solanacearum* into groups based on genetic relatedness. They have allowed rapid identification of unknown isolates, and provided information on the evolution and epidemiology of individual strains. Total genomic DNA restriction analyses of isolates conforming to biovars 1, 2, N2 and 3 have been used to establish the current distribution of individual strains, to reconstruct their possible origins and subsequent dissemination. In some cases, individual *P. solanacearum* strains were shown to have restricted natural geographic distributions and/or plant hosts. The established classification schemes of biovars and races were confirmed by this analysis, with the exception of race 1, which cut across biovars and genetic groups.

PSEUDOMONAS solanacearum is a complex and heterogeneous species group. Its wide host range (Kelman 1953; Buddenhagen et al. 1962), the variability in its biochemical properties (Hayward 1964; Harris 1972), serological reactions (Coléno et al. 1976; Schaad et al. 1978) membrane proteins (Dristig and Dianese 1990), and phage susceptibility (Okabe and Goto 1963) all show that the species is composed of a number of quite distinct strains. Such diversity poses a number of problems, particularly in the production of resistant cultivars, where strain diversity may explain the failure of many attempts to breed universally resistant lines (Thurston 1976; French and de Lindo 1982). Although the species occurs worldwide, the distribution of individual strains is not uniform, and consequently resistant cultivars produced in one geographic area need not be resistant to bacterial strains in another. The circumscribed distribution of some virulent strains poses problems for quarantine authorities who want to identify and exclude these from their own country.

There has always been considerable interest in schemes for subdividing the species, since the properties of unknown isolates might be predictable if groupings based on ecological or physiological characters accurately reflected the overall biological properties of strains. Two schemes have gained wide acceptance for subdividing *P. solanacearum*. These are the race and biovar classifications. The race system groups isolates according to host range and colony morphology. Race 1 strains are pathogenic on solanaceous hosts, diploid bananas and other plants such as peanuts, olives and ginger; race 2 strains are restricted to triploid banana and *Heliconia* spp.; race 3 strains affect potato and occasionally tomato, but are not virulent on other crops (Buddenhagen et al. 1962). The biovar scheme divides the species into four groups based on the ability of strains to metabolise specific disaccharides and hexose alcohols (Hayward 1964).

*Biological and Chemical Research Institute, NSW Agriculture, PMB 10, P.O. Rydalmere, NSW 2116, Australia

The biovar and race schemes attempt to establish meaningful categories on the basis of phenotypic characters, but there is little apparent correlation between the two, except that race 3 may be equivalent to biovar 2 (Buddenhagen and Kelman 1964; Buddenhagen 1986). This lack of concordance is perhaps not suprising, since the race system is based on ecological categories, while the biovar system is based on classical phenotypic characters.

DNA-based Methods for Differentiating Bacterial Strains

Advances in DNA technology mean that it is now possible to identify bacterial strains, to define taxonomic schemes that accurately reflect phylogenetic relationships, and to conduct sensitive epidemiological investigations, solely on the basis of DNA manipulations. The more useful DNA techniques utilise type II restriction endonucleases. These enzymes recognise and cleave specific DNA sequences, resulting in a complex mixture of fragments when genomic DNA is digested. This process is highly repeatable; digestion of the same DNA with the same enzyme will always result in exactly the same fragments. These DNA fragments can be separated according to size using electrophoresis such that each of the thousands of individual fragments migrates to a different position on the gel. All (or a large proportion) of these fragments can be detected using direct staining techniques (genomic fingerprinting—Hartung and Civerolo 1987), or the fragments produced from specific genes can be detected using hybridisation with labelled DNA probes (RFLP analysis = Restriction Fragment Length Polymorphism—Lazo et al. 1987; Cook et al. 1989).

Genomic fingerprinting and RFLP analysis have already been used to identify strains and investigate populations of plant pathogenic bacteria, including *Erwinia* (Cother et al. 1992), *Xanthomonas* (Hartung and Civerolo 1987; Lazo et al. 1987; Gabriel et al. 1988; Broadbent et al. 1992), and *Agrobacterium* (Gillings and Ophel 1992). In each case, bacterial populations were shown to consist of a number of distinct clonal lines that often had restricted host ranges or geographical distributions.

DNA Studies on *Pseudomomas solanacearum*

The solid framework of a DNA-based phylogeny for *P. solanacearum* has already been laid down by Cook et al. (1989). These authors used hybridisation with a panel of DNA probes that specified virulence or the hypersensitive response, to define 28 RFLP groups. This analysis could be used to predict the race and biovar of unknown isolates. Examination of the relationships between RFLP groups showed *P. solanacearum* was composed of two genetically distinct Divisions, found in Australasia and the Americas. The number of RFLP groups has since been expanded to 33 (Cook et al. 1991), and it is certain that this number will continue to grow as more isolates are examined.

Our laboratory uses a genomic fingerprinting technique to identify *P. solanacearum* clones. By analysing *P. solanacearum* isolates that have also been examined by Cook et al. (1989, 1991), we have been able to accumulate a reference library of known RFLP groups such that our work can be directly related to the work at the University of Wisconsin, Madison. Essentially, the correspondence between Cook et al. (1989, 1991) RFLP groups and our genomic fingerprint types is exact. Hence, their RFLP terminology is used in the remainder of this paper. To avoid confusion, subspecific categories referred to in the remaining text will be used in the following senses. In descending hierarchical order: the species *P. solanacearum* is composed of two divisions (*sensu* Cook), each of which can be subdivided into biovars (divison 1 = biovars 3–5; division 2 = biovars 1, 2 and N2). Biovars can, in turn, be divided into RFLP groups (*sensu* Cook). In some instances, RFLP groups can be further subdivided into distinct clonal lines using genomic fingerprinting (Fig. 1). Such clones have been designated by letters appended to the numerical RFLP groups. We use the term isolate to refer to individual cultures and strain to refer to a group of isolates with the same phenotypic properties. Although there may be exceptions to this general scheme, it is a useful working arrangement.

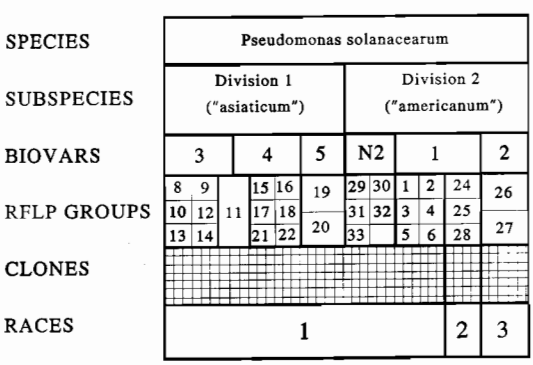

Fig. 1. Generalised scheme for infrasubspecific relationships within *Pseudomonas solanacearum*. The data used to construct this scheme has been derived from many sources, including Buddenhagen et al. 1962; Hayward 1964; Cook et al. 1989, 1991; Hayward et al. 1992; and our own research.

Genomic fingerprinting

When total genomic DNA is digested with restriction enzymes, the average size of the fragments generated depends on the type of restriction enzyme employed and, to a lesser extent, on the GC content of the target DNA. An enzyme recognising a 6 base pair (bp) sequence produces an average fragment size of 4096 bp, whilst those recognising 4 bp cleavage sites produce fragments with an average fragment size of 256 bp. Since most organisms have genomes with large amounts of DNA in comparison to these average fragment sizes, it will be appreciated that any particular restriction digest may contain many thousands of unique restriction fragments. In practice, this usually means that separation of restriction digests using electrophoresis produces a smear of fragment sizes with little or no recognisable pattern, and few individually recognisable fragments.

Bacteria, on the other hand have fairly small genomes, usually between 4 and 6 million base pairs in length. The genome of *P. solanacearum,* for instance, consists of approximately 5 million base pairs. This means it is possible to resolve the relatively fewer fragments produced by digestion of bacterial DNA, especially when optimum combinations of enzymes, separation media and staining techniques are used. Although it is possible to perform genomic fingerprinting analysis using 6 bp enzymes, agarose electrophoresis, and ethidium bromide staining, we find that the best resolution and sensitivity to variation is obtained when bacterial DNA is digested with enzymes that recognise 4 bp sequences; the digests are resolved on polyacrylamide gels, and individual bands visualised using silver staining (Cother et al. 1992; Broadbent et al. 1992). Using this technique, the majority of the fragments can be electrophoresed from the bottom of the gel, allowing just the high molecular weight fragments of the digest to be analysed. It is the analysis of these high molecular weight fragments that gives this particular method its sensitivity. The larger a restriction fragment, the more likely it is to participate in events that might alter the restriction pattern, such as mutation, deletion, and inversion.

Hence, the larger restriction fragments in a digest are a more sensitive measure of existing and newly arising variation. It is this factor that gives our particular method its sensitivity and its ability to discriminate between even closely related strains of *P. solanacearum.*

The uses of genomic fingerprinting

Various important questions about the evolution and population structure of *P. solanacearum* remain essentially unanswered (Buddenhagen and Kelman 1964; Buddenhagen 1986). What are the origins and natural hosts of particular *P. solanacearum* strains? What are the current distributions and means of dissemination of these strains? How closely do the biovar and race schemes reflect the evolution of the species? We believe that genomic fingerprinting studies can give preliminary answers to all these questions, and will use some of our recent research to illustrate this belief.

Case study 1: bacterial wilt of potato, race 3/biovar 2 strains. Bacterial wilt caused by biovar 2 or race 3 strains of *P. solanacearum* is a significant disease of potatoes in many regions. It has often been suggested that the race 3 strains originated in the high Andes, perhaps coevolving with the wild potato (Buddenhagen 1986). Other authors have provided evidence suggesting race 3 may be endemic elsewhere (Seneviratne 1969). There is probably a correspondence between biovar 2 strains isolated in the Andean highlands and race 3 strains, but biovar 2 strains collected in the Amazon basin (Martin et al. 1981) have different phenotypic properties both in terms of pathogenicity on various *Solanum* species (Torres et al. 1985) and in metabolic activity. This second phenotype has been designated biovar N2 (Hayward et al. 1990) to draw attention to these differences.

Questions posed about the biogeography and evolution of race 3/biovar 2 strains might include the following: Did race 3 coevolve with the potato in the high Andes? What is the relationship between biovars 2 and N2, and do these groups both correspond to race 3? Are the occurrences of race 3 strains on potatoes in Africa, Asia and Australia indigenous or exotic organisms? We attempted to answer some of these questions by examination of a collection of biovar 2 isolates using total genomic fingerprinting.

Biovar 2 isolates all belonged to RFLP 26 or 27, and simple inspection of the restriction patterns showed that these two RFLP groups were closely related. Hence the biovar 2 ('highland') strains of the potato pathogen form a distinct group. Biovar N2 ('lowland') isolates generated restriction patterns corresponding to RFLP groups 29, 30, or 32. These patterns exhibited little similarity to RFLPs 26 and 27 or to each other, demonstrating that biovar N2 is a genetically heterogeneous group of strains, despite their apparently homogeneous phenotype (Hayward et al. 1990, 1992).

Of the 54 biovar 2 and N2 isolates examined, 34 belonged to a single clonal line, RFLP 26A. This clone was found in many potato-growing areas of the world, including Australia, Brazil, Egypt, Greece, India, Israel, Kenya, Nepal, Portugal and Sri Lanka. Very minor variations on this restriction pattern were found in Australia (RFLP 26B), Southeast Asia (RFLP 26C), Sweden (RFLP 26D) and Peru (RFLP 26E). All other biovar 2 or N2 RFLP groups were found only in South America. Since RFLP 27 is genetically almost

identical to RFLP 26, and the former group is restricted to South America, the conclusion must be made that RFLP 26 also originated on this continent, since the chance of independent evolution of such similar genomic fingerprints is negligible.

The dissemination of RFLP 26 to other continents presumably occurred due to movement of infected, but symptomless, potato seed, since latent infections can occur (Ciampi and Sequeira 1980; Ciampi et al. 1980, 1981). The reason that RFLP 26 has been widely disseminated while RFLP 27 apparently has not (even though it is similar genetically and phenotypically) may lie in the natural distribution of the clones within South America. RFLP 26 is found east of the Andes watershed, while RFLP 27 is found to the west. It may be that the original dissemination of RFLP 26 occurred during the Spanish conquest, as suggested previously (Buddenhagen 1986), since explorers entered and left South America via the east (Burton 1966), where RFLP 27 does not occur.

This case study confirms the conclusions made by previous workers on the origin and dispersal of biovar 2. Since most biovar 2 isolates were found on potato or tomato the correspondence of race 3 and biovar 2 seems confirmed. However, biovar N2 is probably not equivalent to race 3 since it was found on other *Solanum* species (such as nightshades), and it does not occur in the region where potatoes originated.

Case study 2: identification of race 2 strains in symptomless Heliconia. Bacterial wilt of plantain and triploid bananas (Moko disease), is caused by race 2 strains of *P. solanacearum*. These strains conform to biovar 1, but conversely the majority of biovar 1 strains do not belong to race 2. In the 1960s research directed towards identifying the source of inoculum and the means of disease spread showed that the bacterium could be spread by insects and that the natural host of race 2 strains was probably wild *Heliconia* species (Buddenhagen 1960; Sequeira and Averre 1961). It was suggested that the separate outbreaks were caused by separate strains of race 2 with different geographic distributions (Sequeira and Averre 1961; Buddenhagen and Elsasser 1962). How true were these conclusions and can DNA analysis confirm them?

Because of the possibility that *Heliconia* could act as carriers of bacterial strains capable of causing Moko disease, Australian quarantine authorities have been cautious about the introduction of *Heliconia* and, since 1987, have required that phytosanitary certificates accompany imported *Heliconia* if post-entry quarantine time is to be minimised. In 1989, it was reported that *P. solanacearum* had been isolated from *Heliconia* on Oahu, Hawaii, the major source of *Heliconia* being brought into Australia.

As a result of this discovery, *Heliconia* imports were suspended and all *Heliconia* imported over the previous 2 years were recalled for bacterial testing. Steve Akiew and colleagues at the Queensland Department of Primary Industries found five plants amongst a batch of 367 rhizomes imported from Oahu during April 1989 that tested positive for *P. solanacearum* (Hyde et al. 1992). One of the plants had already been released from quarantine, while the remaining four were still in post-entry quarantine glasshouses. Only three of the positive plants exhibited any symptoms. Biochemical testing of the isolates showed that they conformed to biovar 1 (Hyde et al. 1992), which does not occur in Australia. To determine if the strains were capable of causing Moko disease (race 2), we compared the genomic fingerprints of the unknowns to a reference panel of biovar 1 strains known to belong to race 1 or race 2 (Gillings 1992). Race 1 strains generated diverse fingerprints. The race 2 strains examined produced only 3 genomic fingerprint types, corresponding to RFLP groups 24, 25 and 28 of Cook et al. (1989). The isolates from the imported *Heliconia* were a clone belonging to RFLP group 28 and had a very high similarity coefficient to isolates collected from Moko diseased banana or plantain in Venezuela and Trinidad during the 1960s. This identification was confirmed by work performed at the same time at the University of Wisconsin. Because the genome of the unknown was so similar to RFLP 28, it was likely that they had similar phenotypic properties. In was not until much later that we showed the isolates were capable of causing Moko disease when inoculated into bananas. This potential outbreak shows how DNA-based methods can generate rapid and specific information about the identity of unknown strains, and predict their properties.

How do these results tally with those of previous workers, and what do they tell us about the evolution and epidemiology of *P. solanacearum* strains capable of causing Moko? Firstly, race 2 seems to be a natural grouping of strains, distinct from the other members of biovar 1. Secondly, the distribution of each individual RFLP type is restricted to particular areas within Latin America. These distribution data alone suggest a Latin American origin for race 2 strains. The genomic fingerprinting data clearly show that the epiphytotics during the 1960s were caused by three quite distinct RFLP groups.

The isolation of race 2 from symptomless *Heliconia* agrees with reports (Sequeira and Averre 1961) that these plants are probably the natural hosts of race 2 strains. The susceptibility of banana (which originated in Asia) to bacterial RFLP groups indigenous to Latin America highlights an important plant health issue. As crops are moved around the globe, it seems likely that

more examples of first contact diseases will be recorded, especially when virgin land is cleared for production of exotic crops, and especially when those crops are grown under different environmental conditions from those in their country of origin. Indeed, the recently reported wilt diseases of Australian native plants such as *Eucalyptus* in Brazil (Dianese et al. 1990) and *Casuarina* in China (He 1986) would seem to be good examples of this phenomenon. The identification of the natural hosts of these RFLP groups is of prime importance to Australian quarantine authorities, who would like to prevent these strains entering Australia. The dissemination of *P. solanacearum* strains via distribution of symptomlessly infected planting material should concern all countries currently importing known, or suspected, hosts of the bacterium.

Case study 3: RFLP group 10 in Australia. During the extensive screening of *Heliconia* following the introduction of RFLP 28 into Australia, a number of plants with wilt symptoms were found to be infected with biovar 3 strains of *P. solanacearum*, rather than biovar 1 (Diatloff et al. 1992). We analysed these isolates using genomic fingerprinting and compared them with other biovar 3 isolates from our reference collection and from collections made along the northern and eastern coasts of Australia (Gillings 1992). A total of 42 isolates was examined, all of which belonged to RFLP group 10 (Cook et al. 1989), but could be subdivided on the basis of genomic fingerprinting into a number of clonal lines. RFLP 10A was found on a wide range of hosts including *Strelitzia*, eggplant, black sapote, tomato, potato, tobacco, and *Heliconia*. RFLP 10C was found mainly on *Heliconia*, but was also found on Alexandra palm, an Australian native. RFLP 10D was found only on *Heliconia*. The wide distribution, genetic diversity, and the number of naturally infected hosts of RFLP 10 in Australia all suggest that the group is indigenous. Hence the wilt diseases of the hosts listed, with the exception of the Alexandra palm, could all be regarded as first contact diseases, where an exotic host is infected by a native bacterium. The endemic status of RFLP 10 agrees with the Australasian distribution of biovars 3 and 4 (Division 1)(Cook et al. 1989).

Polymerase Chain Reaction

The Polymerase Chain Reaction (PCR) is a powerful tool for selectively amplifying a particular DNA sequence (Saiki et al. 1985; Mullis et al. 1986). The method utilises two short synthetic DNA molecules, called primers, that are homologous to either end of the gene of interest. When purified genomic DNA is melted into two single strands and cooled in the presence of primers, these can bind (anneal) to the homologous regions of the gene under normal base-pairing rules. Annealed primers act as initiation sites for DNA replication. The newly replicated DNA can then be remelted by heating, and upon cooling, the excess primers present in the reaction mix can anneal to the same homologous regions, thereby initiating the reaction again. Ordinarily, DNA polymerases would denature and become inactivated during the heating step, but it is possible to use one of a number of DNA polymerases from thermophilic organisms that are stable at the temperatures required to melt DNA. Utilising a heat-tolerant enzyme, it is possible to perform multiple rounds of melting, annealing and polymerisation, thereby selectively replicating the region of DNA between the primers. With multiple rounds of replication, a geometric increase in the number of newly synthesised DNA fragments is obtained. The quantities of DNA produced mean that it is possible to detect and analyse specific genes using conventional agarose electrophoresis.

PCR and *P. solanacearum*

PCR has a number of advantages for the analysis of bacteria. Because of its potential sensitivity, it can be used as a detection method, and then the amplified product further analysed to identify the strain involved. It is also a very rapid technique, potentially requiring less than one day to detect and analyse specimens. PCR is not dependent on the use of purified DNA, in fact the best preparation method involves simply boiling 5 µL of a 10^7 cfu/mL cell suspension. This has obvious advantages for analysis of *P. solanacearum*, where cultures can be maintained and distributed as distilled water suspensions.

To detect *P. solanacearum* using PCR we have designed primers based on the published DNA sequence of the gene for endopolygalacturonase (*peh* A—Huang and Schell 1990). We believe that it is important to target a gene with a known contribution to the aspect of the species being investigated (in this case pathogenicity), and one that could reasonably be expected to be present in all strains of interest. Our PCR assay amplifies *peh* A from all races and biovars of *P. solanacearum* tested, but does not amplify DNA from the related species *P. pickettii, P. gladioli, P. cepacia* or *P. pseudomallei*. Successful amplifications have been performed from purified DNA, from pure culture suspensions, and from crude preparations made by suspending infected plant tissue in water.

The PCR assay produces a DNA fragment of 504 bp which has been confirmed as being part of the polygalacturonase gene by DNA sequence analysis. By digesting the fragment with the restriction enzyme *Hae* III, we have defined 6 restriction fragment length polymorphism (RFLP) groups that reflect the known

genetic makeup of *P. solanacearum*. Three of these groups correspond to the 3 RFLP groups of race 2 isolates (RFLP 24, 25 and 28). The fourth group contains all biovar 3 or 4 isolates examined, while the fifth group contains all biovar 2, N2 and the majority of biovar 1/race 1 isolates. The final group contains the type strain (K60) and other isolates from the southern USA that also belong to RFLP group 1. The PCR work therefore confirms the general relationships first proposed by Cook et al. (1989). A major advantage of this form of analysis is the time taken to presumptive strain identification, usually less than 2 days, without the need for culturing. PCR assays of this type will undoubtedly become an important diagnostic tool for epidemiological, quarantine and resistance-breeding studies.

The Future—Some Predictions and Speculations

Examination of *P. solanacearum* strains at the DNA level has clarified the relationship between strains and the validity of current subspecific classification schemes. The major genotypic groups (divisions) are absolutely correlated with the major phenotypic groups (biovars), in that division I contains biovars 3, 4 and 5, while division II contains biovars 1, 2 and N2 (Cook et al. 1989, 1991; also see Fig. 1). Biovar 2 is composed of two RFLP groups, 26 and 27, and seems to correspond exactly with race 3. The genotypic differences between RFLPs 26 and 27 are correlated with differences in phenotype and geographic distribution. A single clonal line of this group, RFLP 26A, is responsible for the majority of records of biovar 2 outside South America.

Strains of the banana and plantain pathogens (race 2) belong to one of three known RFLP groups, RFLPs 24, 25 or 28. Race 2 would therefore seem to be a well defined sub-group of biovar 1 strains within Division II. The same cannot be said of other biovar 1 strains, which are heterogeneous at the DNA level. Likewise, the race 1 classification cuts across division and biovar classifications, and while useful as a general indication of the host range of individual strains, does not reflect any evolutionary or phylogenetic relationship.

The picture that is emerging is that *P. solanacearum* is a complex species composed of a large number of genetic groups each of which can be subdivided into a number of clonal lines (see Figure 1). In many cases, the genetic groups (RFLP groups) have restricted hosts ranges, restricted geographic distributions, or both (Cook et al. 1989, 1991; Gillings 1992). As more isolates are closely examined, it may well be that the apparent complexity of the species will resolve into a number of well circumscribed genetic groups with predictable and uniform properties. Whether these groups should be formally recognised is a matter for discussion. Already it would seem possible for two pathovars to be raised: pv. *solanacearum* (or *tuberosum*?) (for race 3, biovar 2, RFLPs 26 and 27), and pv. *musacearum* (for biovar 1, race 2, RFLPs 24, 25 and 28). Alternately, it might be possible to erect subspecies that recognise the two major divisions of the species as subspecies. However, this scheme would obscure the two groups for which the most information is known—the race 3 and race 2 groups mentioned. Whatever is decided will require consultation amongst the many workers with an interest in bacterial wilt.

It does seem likely that DNA methods will continue to supply us with a clearer picture of the biogeography and evolution of *P. solanacearum*. These studies also allow some predictions to be made about the future of bacterial wilt research. There will be a continual increase in the number of plant hosts recorded as more 'first contact' diseases are described. In most cases, these strains will be new, or undescribed RFLP groups. As more workers examine pristine environments and search for the natural plant hosts of particular strains, a yet more diverse picture of the species will emerge. Studies of the natural hosts and niches of *P. solanacearum* strains will be accelerated by using the sensitive polymerase chain reaction (Saiki et al. 1985; Mullis et al. 1986) to detect low numbers of bacterial cells in the environment. PCR also offers the opportunity to re-examine archival material held as herbarium specimens, where no extant culture is available. Studies such as these may allow us to reconstruct the evolutionary history of this complex species, and be in a better condition to make predictions about its behaviour and control.

Acknowledgments

Thanks to Chris Hayward, Department of Microbiology, University of Queensland, Australia; John Young, Department of Scientific and Industrial Research, Auckland, New Zealand; Steve Akiew and Lex Diatloff, Queensland Department of Primary Industries, Indooroopilly, Australia; and Jose Dianese, Universidade de Brasilia, for supplying cultures and helpful advice. Thanks are also due to Luis Sequeira, University of Wisconsin, Madison and Douglas Cook, Texas A & M University, for access to their unpublished data.

Phylogeny of Biovars of *Pseudomonas solanacearum* Based on Sequencing of 16S rRNA

Xiang Li, M. Dorsch, T. Del Dot, L.I. Sly, E. Stackebrandt and A.C. Hayward*

Abstract

Sequence comparison of ribosomal RNAs (rRNA) or rDNAs extracted from organisms representing the whole range of taxonomic ranks allows delineation of evolutionary relationships. Using the polymerase chain reaction and dideoxy chain termination techniques, the 16S rDNA of four different biovars of *P. solanacearum* and of some other rRNA of group II pseudomonads were amplified and directly sequenced. The sequence data were used as the basis for discerning evolutionary relationships. Strains of *P. solanacearum* representing biovars 1, 2, 3, and 4 showed 0.7% sequence dissimilarity. Biovars 3 and 4 grouped in one cluster with 0.1% sequence divergence, and biovar 1 and 2 had 0.3% divergence in another cluster, which was clearly shown in the phylogenetic dendrogram generated from sequence dissimilarity values. The clusters formed were similar to those obtained by restriction fragment-length polymorphism by other scientists and probably reflect evolutionary divergence and geographic distribution of the species. The sequence results supply further evidence for the separation of biovars 1 and 2 from biovars 3, 4 and 5, the former being primarily of American and the latter of Asian origin. *P. solanacearum* and *P. pickettii* were phylogenetically closely-related species and had 2.3% sequence dissimilarity; both species had 9.4% and 9.6% sequence dissimilarity from *P. cepacia* representing another genetic cluster of the rRNA group II pseudomonads in the beta subclass of the Proteobacteria.

PSEUDOMONAS solanacearum causes bacterial wilt on several hundreds of species representing more than 44 plant families. Based on the differences in host range, colony form and metabolic properties, *P. solanacearum* strains have been subdivided into 5 biovars and 3 races (Buddenhagen and Kelman 1964; Hayward 1991).

To better understand the phylogenetic relationship within the species, we analysed the 16S rRNA sequence data of 4 strains of *P. solanacearum* representing biovars 1, 2, 3 and 4 comparing them with those for some other rRNA group II pseudomonads. The results for *P. solanacearum* are reported in full here and those for the other species representing this group will be reported elsewhere (Li and Hayward, these proceedings).

Materials and Methods

Four strains of *P. solanacearum* representing biovars 1 (Type strain, K60=PDDCC 2712. PDDCC: Plant Diseases Division, DSIR, Auckland, New Zealand), 2 (ACH 0158, ACH: A.C. Hayward), 3 (ACH 0171) and 4 (ACH 092) were identified using both conventional bacteriological tests and the Biolog Identification System (Li and Hayward 1993). Bacterial genomic DNAs were extracted using Marmur's procedures (Marmur 1961) with minor modification (Sly et al. 1986).

Polymerase chain reaction (PCR) was carried out as described by Weisburg et al. (1991), and PCR products were purified using the Prep-A-Gene Kit (Biorad).

Dideoxy chain termination methods followed the Sequenase Version 2.0 Kit (United States Biochemicals) with minor modifications (Dorsch and Stackebrandt 1992). Sequencing products were separated and autoradiographed using standard techniques.

Results and Discussion

The determined sequence data, which covered about 95% of the 16S rRNA molecules of the 4 strains of *P. solanacearum*, was deposited in EMBL/GenBank. After removing the stretches of alignment uncertainties and positions of undetermined nucleotides, a distance matrix (Table 1) was computed between

*Centre for Bacterial Diversity and Identification, Department of Microbiology, University of Queensland, Queensland 4072, Australia.

range base positions 50-1372 (*E. coli* numbering system—Woese et al. 1983) from the percent similarity using the correction of Jukes and Cantor (1969). A phylogenetic dendrogram (Fig. 1) was constructed with average linkage clustering from the distance matrix by the algorithm of De Soete (1983). The sequence data of *P. pickettii* (Li et al. 1993) were used as an outgroup while those of *P. cepacia*, contained in the National Scientific Foundation (NSF) Ribosomal Database Project, were used as the root.

The four biovars of *P. solanacearum* were subdivided into two clusters (Fig. 1) on the basis of the sequence distance matrix (Table 1). The locations and identities of the residues of sequence differences among biovars are shown in Table 2. The major differences between the two clusters were in positions 458–474 (*E. coli* numbering system), which might have the diagnostic potential for developing biovar-specific probes.

The four strains of *P. solanacearum* showed less than 0.7% sequence dissimilarity among them. Strains of biovars 3 and 4 had almost identical sequences (Table 2) in cluster I, and biovars 1 and 2 had 0.3% divergence (Table 1) in cluster II. The results are equivalent to those obtained by restriction fragment-length polymorphism (RFLP) (Cook et al. 1989) and confirmed the conclusion that biovars 1, 2, and 3, 4, 5 reflected phylogenetic or evolutionary relationships within the species, as well as the geographic distribution of the bacteria. The sequence results are also consistent with numerical taxonomic analyses using various procedures (Engelbrecht and Hattingh 1989; Li and Hayward 1993). Nutritionally, biovars 1 and 2 are less versatile than biovars 3 and 4 (Hayward 1991).

Pseudomonas solanacearum and *P. pickettii* were shown to be closely related species and had 2.3% sequence divergence. Both species have similar phenotypic properties (Hayward 1991), fatty acid fingerprints (Janse 1991), and DNA–RNA and DNA–DNA homology (De Vos and De Ley 1983; Palleroni 1984), which differed from the other rRNA group II pseudomonads. *P. solanacearum* and *P. pickettii* had 9.4% and 9.6% sequence divergence with *P. cepacia*, a member of another subgroup of the rRNA group II pseudomonads. The relationship between these two species and other members of the rRNA group II pseudomonads and the beta subclass of Proteobacteria are discussed elsewhere (Li et al. 1993).

Conclusion

This study provides phylogenetic evidence in support of the conclusion (Cook et al. 1989) that *P. solanacearum* comprises two clusters. Cluster I containing biovars 1 and 2 is primarily distributed in Americas. Cluster II containing biovars 3, 4 and most likely 5 is of Asian origin. Both groups may be potentially regarded as subspecies.

Strain Differentiation of *Pseudomonas solanacearum* by Molecular Genetic Methods

D. Cook* and L. Sequeira†

Abstract

Traditionally, strains of *Pseudomonas solanacearum* have been organised into three races based on host range, and five biovars based on the oxidation of certain sugars and sugar alcohols. Although this type of analysis has proven useful to catalogue diversity within the species, it has provided little basis for understanding the origin and significance of this diversity. We previously used restriction fragment length polymorphism (RFLP) analysis of 62 strains of *P. solanacearum* as the basis for a new classification scheme. In this study we extend the RFLP analysis to include 102 additional strains. We demonstrate that although most of the strains we analysed are members of previously defined RFLP groups, thus confirming the utility of this technique, some of the strains are associated with newly defined RFLP groups. RFLP groups are most strongly correlated with geographical origin of the strain, and to a lesser extend with the host of origin. From analysis of the data we are able to tentatively identify two general classes of RFLP mutations: those which are recurrent, and therefore indicate either parallel or convergent evolution; and those which are non-recurrent, probably rare events that indicate divergence between populations.

Development of Molecular Diagnostic Techniques for Detection of *Pseudomonas solanacearum* and Identification of Subgroups within this Species

S. Seal*, L. Jackson† and M. Daniels†

Abstract

The aim of our research is to develop nucleic-acid-based diagnostic methods for detecting the presence of *Pseudomonas solanacearum*, and for rapidly differentiating subgroups within this pathogen. A species-specific DNA probe, selected by subtraction hybridisation, was shown in field trials in Burundi to be a useful tool for screening potato stems and tubers for bacterial wilt infection. However, the detection limit of the probe is 105-106 cells and so this test would not be suitable for detecting latent infection. Sequencing the species-specific DNA allowed the construction of oligonucleotide primers that can be used for detecting the presence of 100 or fewer *P. solanacearum* cells by polymerase chain reaction (PCR) amplification. The relationship of *P. solanacearum* to the blood disease bacterium (BDB), the Bugtok bacterium and the Sumatra Clove disease bacterium (*Pseudomonas syzygii*) was studied by RFLP analysis and partial 16S rRNA sequencing. The latter has allowed the construction of oligonucleotide primers specific for *P. solanacearum*, *P. syzygii* and the BDB, which can detect as few as one cell after 50 rounds of PCR amplification. Fingerprints produced by PCR amplification with tRNA consensus primers allow the species to be divided into three main subgroups. These groups correspond well with previously reported divisions of RFLP groups.

BACTERIAL wilt on potato and banana is known to have been spread within and between countries in latently infected planting material (e.g. Akiew et al. 1990; Ciampi et al. 1980; Lehman-Danziger 1987; Nyangeri et al. 1984; Olsson 1976). Other crops such as tomato are also capable of carrying latent infections of *P. solanacearum* (Prior et al. 1990). Thus, there is a clear need for sensitive quarantine measures against *P. solanacearum*, not only for tropical and subtropical countries, but also for temperate zone countries where race 3 could be a threat to farmers growing potato (Olsson 1976). The effectiveness of quarantine procedures relies on the use of simple yet sensitive detection techniques. Traditionally, identification methods for *P. solanacearum* have consisted of a series of biochemical tests on purified single colonies, which can take two weeks. More recently, methods such as metabolic profiling (Bochner and Savageau 1977) or computer-assisted fatty acid profiling (Stead 1988), although speeding up the process, still require purification of a single *P. solanacearum* colony which may be obscured by the more rapid growth of other plant-associated microorganisms.

Antibodies, DNA probes and specific primers for polymerase chain reaction (PCR) amplification are tools enabling specific detection of organisms without the need for purification or cultivation. In many instances this is advantageous as selective media have been shown to reduce the efficiency with which micro-organisms are recovered from the environment (Roszak and Colwell 1987). Moreover, some bacteria can enter a non-culturable but apparently viable state (Pickup 1991) and not be detected by traditional isolation procedures.

Work at The Sainsbury Laboratory has concentrated on the development of nucleic-acid-based techniques for detection and identification of

*Natural Resources Institute (NRI), Central Avenue, Chatham Maritime, Kent ME4 4TB, United Kingdom

†The Sainsbury Laboratory, John Innes Centre, Colney Lane, Norwich NR4 7UH, United Kingdom

P. solanacearum. Complementary work at Rothamsted Experimental Station (Harpenden, U.K.) is aimed at the production of specific monoclonal antibodies for *P. solanacearum*.

DNA probes represent an attractive approach to the detection and identification of bacteria and such probes have been developed and applied successfully in the detection and identification of a number of human pathogens and plant-pathogenic bacteria. However, the development of a DNA probe specific for *P. solanacearum* is complicated by a number of factors. Thus, the species *P. solanacearum* shows a high degree of genetic diversity (Cook et al. 1989; Seal et al., unpublished data) as well as a high level of DNA homology to *Pseudomonas pickettii* (Ralston et al. 1973) and the clove disease bacterium *Pseudomonas syzygii* (Bennett et al. 1985; Roberts et al. 1990). *P. solanacearum, P. syzygii* and *P. pickettii* are found within the same DNA–DNA homology group of the Pseudomonas rRNA homology group II (Palleroni 1984; Roberts et al. 1990). In addition, a closely related pseudomonad '*Pseudomonas celebense*' (Gäumann 1923; Eden-Green and Sastraatmadja 1990), which causes blood disease of Musaceae in Indonesia, reacts with antisera raised to *P. solanacearum* and some *P. solanacearum* DNA probes (Cook et al. 1991; Seal et al., unpublished data). In this paper we describe the isolation and field testing of a species-specific probe for *P. solanacearum*.

The taxonomic relationship of *P. solanacearum* to the blood disease bacterium (BDB) and to *P. syzygii* have not been investigated in detail. Welsh and McClelland (1991) designed consensus tRNA primers and a radioactive PCR method for measuring the degree of DNA relatedness at the species and genus level. The organisation of tRNA genes is thought to be reasonably stable over time, and therefore polymorphisms should be fairly consistent within a species and similar between closely related species. We therefore tested the use of their primers in resolving the taxonomic relationship of *P. solanacearum* to *P. syzygii* and the BDB. A modified non-radioactive technique using two of their primers supported a close relationship between these three species and, unexpectedly, also proved to be a useful quick test for grouping strains of *P. solanacearum*.

We also studied the relationship between strains of *P. solanacearum*, BDB, *P. syzygii*, and *P. pickettii* by partial sequencing of the DNA encoding 16S rRNA, a technique useful for taxonomical characterisation of species (Woese 1987). The sequence information allowed the development of a highly sensitive PCR test specific for the group *P. solanacearum, P. syzygii* and BDB.

Materials and Methods

Bacterial strains, culture media and growth conditions

P. solanacearum was routinely cultured at 28°C in CPG broth (Hendrick and Sequeira, 1984) or on CPG plates containing 15 g/L agar and 0.1 g/L 2,3,5,-triphenyltetrazolium chloride. *Escherichia coli* strains were grown at 37°C in LB medium (Miller 1972). All other bacterial species used were grown in NYG medium (Daniels et al. 1984). Whole *P. solanacearum* cells to be used for providing template for PCR amplifications were grown in MM minimal medium (Boucher et al. 1985) to ensure adequate lysis of the cells. Lysis was performed by boiling 100 µL of an overnight MM culture (or a loopful of bacteria from a colony resuspended in 100 µL sterile distilled water) for 5 minutes. After cooling to room temperature, 1–5 µL of the boiled culture was used per reaction without further treatment.

DNA manipulations

Bacterial DNA was isolated by the method of Boucher et al. (1987). The procedures for agarose gel electrophoresis, Southern blotting, preparation of competent cells, ligation and transformation were as described by Maniatis et al. (1982). Restriction enzyme digestions were carried out according to the conditions defined by the supplier. Hybridisations were performed at 65–68°C with probe DNA labelled with digoxigenin-11-dUTP, which was detected by chemiluminescence, according to manufacturer's instructions (Boehringer Mannheim). Plant squashes or blots were made on Boehringer positively charged nylon membranes, which were subsequently placed on Whatman 3 MM paper soaked in 1.5 M NaCl, 0.5 M NaOH for 7 minutes, followed by 5 minutes neutralisation on 1.5 M NaCl, 0.5 M Tris-Cl pH 7.2, 1 mM EDTA. The DNA from the plant squashes was fixed to the membrane either by UV crosslinking or by boiling the membrane for 1 minute in distilled water.

Isolation of a *Pseudomonas solanacearum*-specific DNA probe by subtraction hybridisation.

To avoid laborious screening of randomly cloned DNA fragments for their specificity for *P. solanacearum*, a simple subtraction hybridisation method was utilised. Sequences present in one strain (the 'target' strain) not present in another strain (the 'driver' strain) were enriched by removal of common DNA. *Xanthomonas campestris* pv. *vesicatoria* was used as the driver strain and 250 µg DNA was sheared by ultrasonication (MSE, model Soniprep 150) to a size range of 1–3 kb, and then mixed with 1 µg *Mbo*I-digested *P. solanacearum* UW25 DNA. The mixture was

denatured at 100°C for 5 minutes and then allowed to reassociate for 18 hours at 86°C in 2.4 M phosphate buffer pH 6.8. The reassociated DNA mixture was dialysed extensively against 10 mM Tris-Cl, 1 mM EDTA pH 8.0 (TE), precipitated with ethanol and redissolved in 250 µL sterile distilled water. Ligations of subtracted mixture with phosphatase-treated *Bam*HI-digested pBR322 DNA were carried out overnight at 12°C. Aliquots of the ligation mixture were transformed into competent *E. coli* ED8767 cells and transformants selected on LB plates supplemented with ampicillin (Amp). Transformants containing recombinant plasmids were tetracycline sensitive. Preparation of the insert DNA from the clones was carried out by PCR amplification using oligonucleotide primers corresponding to sequences flanking the *Bam*HI site of pBR322. Sequencing of the clone's inserts was performed using a Sequenase kit (United States Biochemical, Cleveland, Ohio, U.S.A.).

PCR amplifications.

PCR reaction volumes (25–100 µL) contained 1× PCR buffer (10 mM Tris-Cl pH 8.3 at 25°C, 50 mM KCl, 1.5 mM $MgCl_2$, 0.001%(w/v) gelatin (Sigma G-2500), 0.05%(v/v) Nonidet P40 (Sigma N-3516), 0.05%(v/v) Tween 20 (Sigma P-1379)), 0.2 mM of each dNTP, 1.25U Ampli*Taq* polymerase (Perkin-Elmer Cetus)/ 50 µL reaction volume, 1 µM of primers and template DNA. Each reaction was overlaid with two drops of light mineral oil (Sigma M-3516), heated at 96°C for 2 minutes to ensure complete denaturation of the template DNA, and then cycled through a temperature profile. For amplification of the *P. solanacearum*-specific product, primers PS96-H and PS96-I were used. After 2 minutes denaturation at 96°C, 50 µL reaction volumes were cycled 35-50 times through phases of denaturation (94°C for 10 sec), annealing (64°C for 20 sec) and extension (74°C for 20 sec), with a final extension for 10 minutes.

For rapid subgroup identification, the primers T3A and T5A (Welsh and McClelland 1991) were used. Reaction volumes were typically 50 µL and template DNA was either 20–100 ng of purified DNA or from 1–5 µL of boiled culture. Reactions were heated at 96°C (2 minutes) and then cycled 35 times through a denaturation phase (94°C, 10 sec), an annealing phase (48°C, 15 sec) and an extension phase (72°C, 1 minute). Finally the reactions were kept a further 10 minutes at 72°C.

PCR products were resolved by running 15 µL on 2.0% agarose (Sigma, A-6013) gels equilibrated in 1× TBE buffer (8.9 mM Tris, 0.25 mM Na_2EDTA, 0.89 mM boric acid pH8.3), and staining with ethidium bromide. Band sizes were estimated by comparison with a 1 kilobase (kb) size ladder (Gibco-BRL, Cat. No. 520–5615SA).

Partial sequencing of DNA encoding 16S rRNA

A 292 base pair (bp) fragment of the DNAs encoding 16S rRNA of 40 *P. solanacearum*, 4 BDB, 3 *P. syzygii* and 2 *P. pickettii* strains was amplified by PCR using conserved primers for bacterial 16S rDNA. The PCR product was purified using Qiagen 'Tip-5' columns (Diagen GmbH, Dusseldorf, Germany) according to the manufacturer's protocol. Purified products were sequenced in both directions using a T7 sequencing kit (Pharmacia LKB). Sequences were aligned with each other and with respective sequences from related bacteria stored in the EMBL Data Library.

Results

Species-specific probe

Of the 121 clones containing *P. solanacearum* subtracted DNA obtained, 44 had inserts that were large enough (>100 bp) to be labelled adequately with digoxigenin-11-dUTP. The insert PS2096 from one plasmid hybridised to 82 out of 85 tested *P. solanacearum* strains in Southern and cell blots. Three strains (UW119, UW373 and GMI1336) did not hybridise to PS2096 under stringent conditions; neither did 27 strains from other bacterial species.

To determine the sensitivity of this probe, dilutions of exponentially-growing cultures were dotted onto nylon membranes and probed with PS2096 labelled either with ^{32}P-dCTP or with digoxigenin-11-dUTP. PS2096 hybridised to a greater extent to some strains than others, with the limit of detection between 4×10^5 and 4×10^6 cfu/mL. No significant difference was observed between ^{32}P- and digoxigenin-labelling when the latter was detected by chemiluminescence. Although this sensitivity allows PS2096 to be used for rapid identification of *P. solanacearum* and diagnosis of moderately infected plant material, the sensitivity is not considered adequate for detection of low-level latent infections or for quarantine purposes.

PCR amplification of DNA using specific primers has been shown to permit sensitive detection of target organisms. PS2096 was sequenced and determined to consist of 172 bp of *P. solanacearum* DNA. The sequence enabled synthetic oligonucleotide primers, PS96-H and PS96-I, to be constructed. Purified DNA or lysed cells of *P. solanacearum* strains (with the exception of GMI1336, UW119 and UW373), and extracts of wilt-infected potato plants or tomato seedlings inoculated with *P. solanacearum*, gave a characteristic 148 bp product on agarose gels after PCR amplification with primers PS96-H plus PS96-I. PCR applied to purified DNA or cells from other species or to extracts of uninoculated tomato seedlings failed to generate products of any size.

To determine the limit of detection of the PCR assay with primers PS96-H plus PS96-I, dilutions of exponentially growing cultures of five strains were used as template for the PCR reaction. After electrophoresis of aliquots of the PCR reactions (50 rounds), the 148 bp product could be seen from samples containing between 5 and 116 cells, depending on the strain used.

Consensus-tRNA primer PCR test

Three clear subgroups, corresponding to certain race and biovar combinations, were detected within *P. solanacearum* using the primer combination T3A plus T5A (see Fig. 1). All *P. solanacearum* strains produced a low band (~100 bp), and fingerprints produced within this species could be categorised into three main types. Type 1 strains possessed only the low band, type 2 strains always had an additional band just below 200 bp. Type 3 strains gave an additional band at approximately 450 bp (and also usually the 200 bp band of type 2 strains). These three types of pattern correlated well with divisions made in previous studies (Cook et al. 1989; Engelbrecht and Hattingh 1989; Hayward 1964; Palleroni and Doudoroff 1971). Type 3 strains represented biovar 3, 4 and 5 strains and hence corresponded to the Division I made by Cook et al.

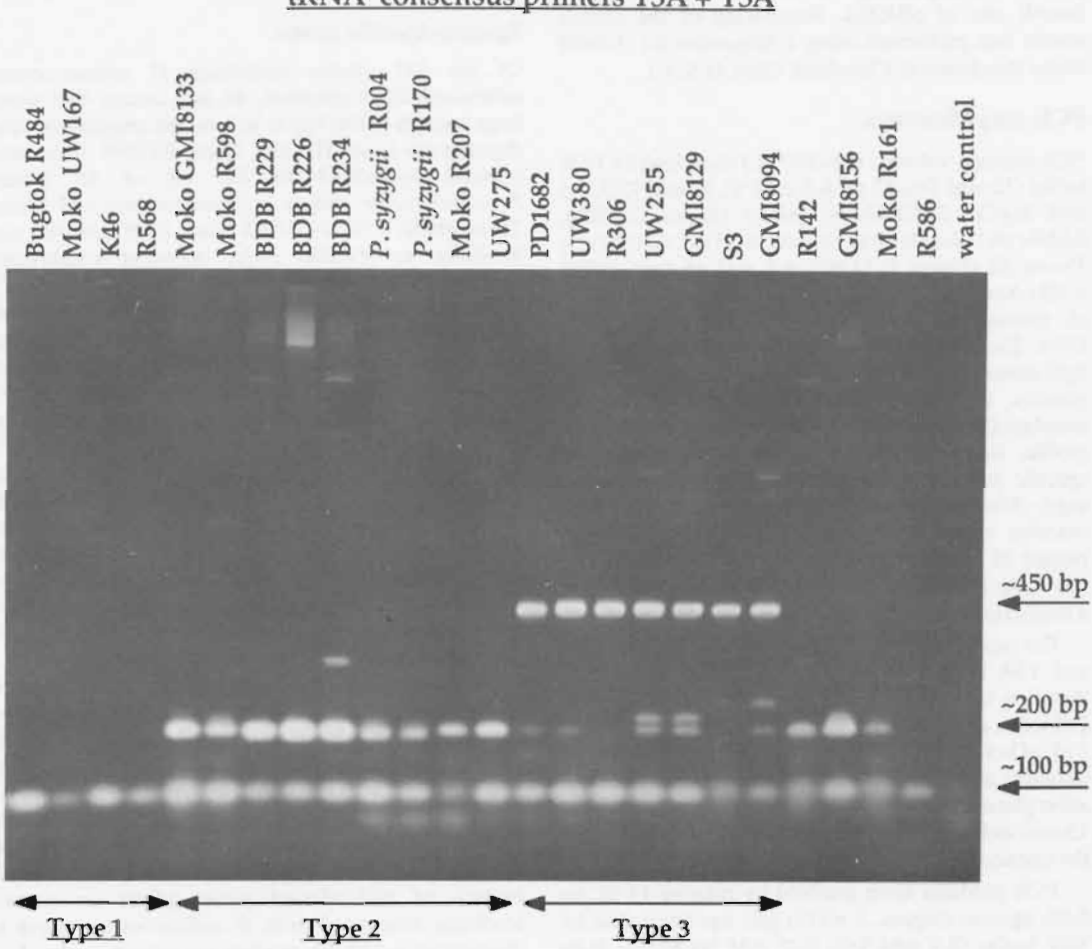

Fig. 1. Fingerprints of *P. solanacearum, P. syzygii* and blood disease bacterium (BDB) strains produced by PCR amplification with tRNA consensus primers T3A plus T5A. Fingerprint bands were resolved by 2% agarose gel electrophoresis and staining the gel with ethidium bromide. Approximate band sizes are marked on the right in base pairs (bp).

(1989, 1991). Their Division II is divided into two subdivisions sharing 30–50% similarity to each other and type 1 and type 2 strains accurately represent these two subdivisions. Hence, type 2 strains are all tested race 1 biovar 1 strains and a subgroup of race 2 strains, whereas type 1 strains represent the other subgroup of race 2, all of race 3 and the lowland biovar 2 strains which have not been designated a race to date. Other combinations of the three tRNA primers designed by Welsh and McClelland (1991) also gave variable PCR patterns, but these could not be correlated clearly to race, biovar or origin of species.

Of 112 *P. solanacearum* strains tested only three strains, R27, R142 and UW378, showed unexpected patterns for their race/biovar and origin. These three strains were from Asia, and two of the three are atypical in other respects; R27 is the only *P. solanacearum* strain studied that does not readily oxidise glucose, and R142 is unusual in being a biovar 2 strain isolated from cloves in Sumatra, Indonesia. Biovar 2 strains are typically isolates from potatoes grown at higher elevations in the tropics. Lowland biovar 2 strains have been found in Brazil, Peru and Nigeria (Cook and Sequeira 1991) but here they were isolated from solanaceous hosts or soil. Moreover, the pattern shown by R142 is type 2 rather than the type 3 shown by all other biovar 2 isolates.

Partial sequencing of DNA encoding 16S rRNA

The sequences of the 40 *P. solanacearum* strains fell into a tight cluster with only 2 variable sites along the 292 bp. Each site had the possibility of 2 bases resulting in a total of 4 groups within *P. solanacearum*. One of these groups had only 2 members and a sequence identical over the 292 bp to that of the BDB strains. *P. syzygii* strains lacked 2 of the 292 bases and hence showed a combination not shown by any of *P. solanacearum* or BDB strains. *P. pickettii* strains showed 11–13 different bases over the 292 bp, compared to 17 different bases between *P. solanacearum* and *Alcaligenes eutrophus*.

Oligonucleotides specific for the group *P. solanacearum*, the BDB and *P. syzygii*, were constructed by sequence comparison with the EMBL Data Library (in particular 16S rRNA sequences of *P. pickettii*, *P. cepacia*, and *A. eutrophus*). The sensitivity of the PCR test was determined as outlined above for primers PS96-H and PS96-I, and found to be able to detect *P. solanacearum* and BDB down to the single cell stage. The sensitivity of the test applied to *P. syzygii* was not determined.

Field trial of probe and PCR primers.

PS2096 was tested on membranes containing squashes of potato stems and tubers collected at field stations in Burundi. PS2096 hybridised to 5 out of 8 samples from wilted plants, but not to the three healthy plant controls as shown in Figure 2. The localisation of *P. solanacearum* cells in the vascular bundles can be observed where stem squashes on the membrane were performed carefully (rows 4, 5, 6 and 10). PCR applied to extracts from healthy field-grown potatoes failed to generate products of any size (Seal et al. 1992). The PCR technique could detect lower numbers of *P. solanacearum* cells in field samples than the probe PS2096; all samples from wilted potato plants, including the three that did not hybridise detectably to probe PS2096 (Fig. 2, row 7, 8 and 9), did produce the specific band with primers PS96-H plus PS96-I after PCR amplification.

Samples from ginger rhizomes, pepper, potato, tomato and eggplant planting material were prepared in Nepal and Indonesia by Dr John Elphinstone, and posted for testing at The Sainsbury Laboratory. The PCR test detected more positives than the probe, and results indicated the wide applicability of the molecular techniques.

Discussion

Three nucleic-acid-based techniques for detection of *P. solanacearum*, BDB, *P. syzygii*, and subgroup identification of *P. solanacearum* have been developed, as follows.

DNA probe

A 172 bp *P. solanacearum*-specific probe PS2096 was isolated by screening 44 subtraction hybridisation library clones against 85 *P. solanacearum* strains and 27 strains from other bacterial species. The 85 *P. solanacearum* strains originated from 49 different host–country combinations and were considered to be a representative sample of the species. Only three non-pathogenic *P. solanacearum* strains, GMI1336, UW119 and UW373, did not hybridise to PS2096 under stringent conditions. These three strains have previously been reported not to hybridise to certain clones containing genes required for pathogenicity and production of a hypersensitive response on an incompatible plant [*hrp* genes (Boucher et al. 1987)]. Strains UW119 and UW373 did not hybridise to three *hrp* clones, pT13, pKD1602 and pK1506, used for RFLP analysis (Cook et al. 1989). In that study, another strain, UW90, also did not hybridise to pT13 or pKD1602, but did hybridise with pK1506. The non-pathogenic strain UW90 did, however, hybridise to PS2096, and thus PS2096 is not a part of either pT13 or pKD1602. It remains possible that it is part of the pK1506. No significant relatedness was found between PS2096 and sequences present in the EMBL–GenBank Data Library, or with the *hrp* clone pVir2 (M. Arlat, S.

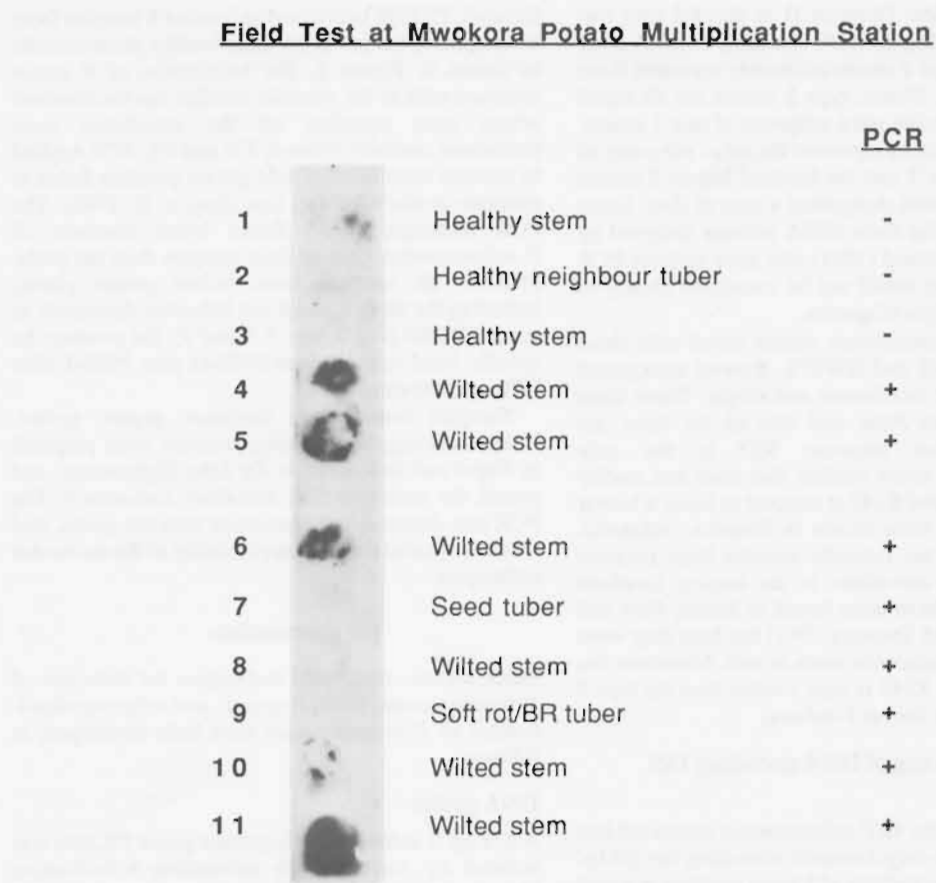

Fig. 2. Field test at Mwokora (Burundi) Potato Multiplication Station: comparison of probe PS2096 and PCR primers for detection of *P. solanacearum* infection in potato. Stem and tuber squashes were made on positively charged nylon membrane, probed with digoxigenin-11-dUTP labelled PS2096 and detected by a chemiluminescent detection method (left side). Water extracts of the same samples were tested by PCR amplification with the *P. solanacearum*-specific primers. Presence of the specific product on agarose gels is denoted by a '+' (right side). BR = brown rot symptoms.

Genin, C. Gough, INRA, Toulouse, pers. comm.). However, many naturally occurring avirulent strains carry large deletions of hundreds of kilobases including the *hrp* genes (Boucher et al. 1987), so it is possible that PS2096 is derived from a region close to the *hrp* genes.

The DNA probe PS2096 offers a rapid and precise identification method, with minimum detection levels of ~10^5–10^6 bacteria. The DNA probe was sequenced, allowing construction of specific oligonucleotide primers for more sensitive detection through the application of PCR technology. Between 5 and 116 cfu of *P. solanacearum* could be detected using primers PS96-H and PS96-I and 50 rounds of amplification. The sensitivity could be improved further by hybridisation of the PCR product with an internal part of the amplified fragment or by a second round of amplification. Either of these methods should bring the sensitivity down to the single cell stage, but runs the increased risk of contamination occurring.

To date, few diagnostic tests for *P. solanacearum* have included strains of *P. pickettii* as controls, as this opportunistic pathogen was not considered to be present in or on planting material. *P. pickettii* is usually

recorded from hospital-acquired human infections arising from contaminated water supplies. However, one isolate E1625, was supplied to our laboratory as originating from a wilt-infected potato field in Ethiopia. As *P. pickettii* colonies have been found on isolations from diseased potatoes in Ethiopia and the pathogen is considered to be commonly found in soils, it is clearly important that probes and other diagnostic tests should discriminate *P. solanacearum* from this species.

tRNA consensus primer test

This PCR test is proposed as a quick technique for subgroup determination, requiring only 5 hours after the isolation of a pure culture of the bacterium. It is not a definitive test for identifying the species *P. solanacearum*, which can be achieved with the probe PS2096 and PCR primers. Nevertheless, most bacterial species produced a tRNA-PCR fingerprint that was clearly distinguishable from the fingerprints produced by *P. solanacearum* strains. For example, strains R215, E110b and E1625 were sent to our laboratory as putative *P. solanacearum* isolates, but subsequently identified not to be by their PCR patterns. This was confirmed by their nutritional characteristics and lack of homology with the *P. solanacearum* specific DNA probe PS2096.

Strain R142's fingerprint is very similar to those of the BDB-strains, including the fainter bands present in the pattern (Fig. 1). However, biochemical properties of strain R142 are more typical of *P. solanacearum* than BDB-strains, which show a different profile of carbon source utilization (Eden-Green and Sastraatmadja 1990). The PCR patterns support close relationship between the BDB strains, *P. syzygii* and *P. solanacearum*, previously suggested by DNA–DNA hybridisation (Cook et al. 1991; Roberts et al. 1990, Seal et al., unpublished data) and serological properties (Hayward 1991; Roberts et al. 1990). *P. syzygii* has been determined to be a separate species (Roberts et al. 1990) and as BDB strains show the same pattern as *P. syzygii* and as type 2 strains of *P. solanacearum*, it cannot be determined if the BDB strains should be classified as a new species or a subgroup of *P. solanacearum*.

Bugtok disease is a serious disease affecting cooking bananas throughout the Philippines. By carbon source utilisation, RFLP analysis and partial 16S rRNA sequencing (Seal et al., unpublished results) the causal organism has been unequivocally shown to be a *P. solanacearum* strain. The PCR fingerprint and our RFLP data suggest that bugtok and Moko banana strains of the Philippines have a common origin with a subgroup of Central American banana strains. This raises an interesting question. Bugtok disease was present in the Philippines (Roperos 1965) a few years before the reported introduction of Moko in banana rhizomes to the Philippines (Buddenhagen 1986), suggesting that either an earlier introduction occurred, or that the Philippine strains were previously imported into Central America. The former seems more plausible as these strains fall into the same group as race 3 biovar 2 strains considered indigenous to South America (Buddenhagen 1986; Cook et al. 1989, 1991).

Biovar 2 (race 3 and unclassified) strains from solanaceous hosts show the same PCR pattern, despite coming from countries scattered around the world. This supports beliefs (Buddenhagen 1986; Cook et al. 1989, 1991) that race 3 spread extensively via infected potato tubers throughout the world, and also suggests that the lowland biovar 2 strains have a common origin with the highland race 3 strains.

The banana strain R204a was obtained from the International Mycological Institute (CMI #B8605) and was deposited as an isolate from wilt-infected banana in India. The similarity of the fingerprint of R204a, including the fainter bands, with the banana strain R581 from Honduras suggests that these two strains may have a common origin. However, the status of bacterial wilt of banana in India has not been confirmed (Buddenhagen 1986) and further isolates from India need to be examined.

This quick test to determine subgroup may be of value in quarantine laboratories, *P. solanacearum* being a quarantine organism for many countries. The introduction of race 3 of *P. solanacearum* on potatoes could be a threat to potato growers in temperate countries, as was illustrated in Sweden (Olsson 1976). A fast test to discriminate this race and the lowland biovar 2s from race 1 biovar 1, 3 and 4 strains, which should not pose a threat in temperate climates, would be useful. Fingerprint types produced by T3A plus T5A amplification support the division of *P. solanacearum* into three subspecies.

The tRNA-PCR test ideally uses samples from purified cultures. However, preliminary tests on crude ooze from diseased potato stems and tubers suggest that the test may be applicable also to direct testing of oozing field samples. Ooze contains high numbers of *P. solanacearum* cells and the fingerprint from these cells should be readable through the faint pattern from trace amounts of other DNAs in the sample.

Partial sequencing of DNA encoding 16S rRNA

The principle of using rRNA sequences to characterise microorganisms has by now gained wide acceptance (Woese 1987). A close relationship between *P. solanacearum*, *P. syzygii*, and *P. pickettii* has been established on the basis of DNA-rRNA hybridisation (Johnson and Palleroni 1989; Ralston et al. 1973;

Roberts et al. 1990). Partial 16S rRNA sequence data confirms these studies and shows BDB strains to also be a member of this cluster. *P. solanacearum* has previously suggested to be a heterogeneous species at the DNA level (Palleroni and Doudoroff 1971; Roberts et al. 1990), and variation in the 16S rRNA sequence data thus supports previous findings.

It is clear from our research that *P. celebense* (the 'blood disease bacterium') is extremely closely related to *P. solanacearum*. However, uncertainty remains as to whether it should be classified as a further subgroup of *P. solanacearum* or a separate species. DNA from *P. celebense* strains hybridised to some *P. solanacearum* DNA probes (Cook et al. 1991; Cook and Sequeira 1991; Seal et al., unpublished data), but not to PS2096 and many others (Seal et al., unpublished data). The BDB strains do not produce any PCR products with primers PS96-H and PS96-I, even when annealing temperatures were reduced from 64°C to 50°C, suggesting that they do not possess a sequence similar to PS2096. Although the tRNA fingerprint data do not allow clear differentiation of the BDB from *P. solanacearum*, this test also does not discriminate between these species and *P. syzygii* (which has been determined to be a closely related, but distinct species). *P. celebense* strains do possess several distinct nutritional characteristics (Eden-Green and Sastraatmadja 1990; Seal et al.,unpublished data) and are unable to wilt tomato seedlings. A more detailed analysis, including complete 16S rRNA sequence determination, is required before the taxonomical position of BDB in relation to *P. solanacearum* can be accurately assessed.

Many questions regarding the epidemiology of bacterial wilt have remained unanswered to date, partly due to lack of a simple, rapid and sensitive identification procedure. Seed has been suggested to be a vehicle for the spread of bacterial wilt, but no conclusive data have been reported (Hayward 1991). Although many weeds have been shown to be symptomless carriers of *P. solanacearum* (Hayward 1991), there are probably also many unknown hosts that maintain high inoculum levels between successive crops. The application of the probe and PCR tests developed should allow these aspects and many other aspects of the epidemiology to be reinvestigated.

Acknowledgments

We would like to thank all who kindly donated strains to our collection, and those who helped with field trials of the nucleic-acid-based tests. This work was commissioned by the Natural Resources Institute, Chatham, U.K., (project X0082) and was carried out under MAFF licence Nos. PHF 1185A/99(81), PHF 1185B/10(111) and PHF 1185A/62(11), issued under the Plant Health (Great Britain) Order, 1987. The Sainsbury Laboratory is supported by the Gatsby Charitable Foundation.

Study of Latent Infection of Potato Tubers by *Pseudomonas solanacearum* in Burundi

L. G. Skoglund*, S. Seal†, J. G. Elphinstone§ and D. E. Berrios**

Abstract

Pseudomonas solanacearum, race 3, is a major constraint to production of potato (*Solanum tuberosum*) in Burundi. A major effort in the control strategy has been to minimise latent infection during field multiplication of seed tuber stocks originating from basic materials multiplied *in vitro*. A collaborative study was undertaken to determine infection frequency in seed stocks by use of NCM-ELISA, a non-radioactive DNA probe, and polymerase chain reaction (PCR) amplification with *P. solanacearum*-specific primers. Comparisons of the techniques were made and sampling techniques were evaluated. A preliminary study showed that all three techniques would detect the pathogen under field conditions (up to 80% positive) and that the best method for sampling was maceration of tuber tissue. In a more detailed study, detection was possible only with PCR in which 3.3% of samples were positive. This indicates that latent infection is highly variable by cultivar, season and year.

BACTERIAL wilt (*Pseudomonas solanacearum* E.F. Smith) is a major constraint to production of potato (*Solanum tuberosum* L.) in Burundi. The predominant race is race 3. The National Potato Program, with assistance from the International Potato Center (CIP), initiated a program to produce high-quality seed free of latent infection. Through a system of rigorous positive and negative selection, crop rotation, sanitation, and downhill flow of seed stocks from high altitudes, it was determined that the amount of wilt was reduced from more than 60% to less than 1% (Autrique 1984, 1987; Rueda-Sarmiento 1991).

There is a need for rapid and sensitive methods to detect *P. solanacearum* in tubers for research and quarantine purposes in Burundi and other developing countries. Polyclonal antibodies have been produced at CIP (Peru), Rothamsted Experimental Station (U.K.), and other locations. Nakashima and Nydegger (1986) found that latex and ELISA tests with polyclonal antibodies were more sensitive and less time-consuming for detection from sap and tubers than culturing on specific medium. Janse (1988) reported the use of an indirect immunofluorescence antibody stain using polyclonal antibodies to be quick, specific and sensitive. This was combined with pathogenicity testing, a time consuming method. Recently, other techniques have become available for field testing.

Materials and Methods

DNA probes and nylon membranes were spotted with 10 µL of extract for NCM-ELISA and DNA probe. The cut surface of the tuber was flooded with 500 µL of sterile, distilled water using a micropipetter. Five microlitres of liquid were placed in a tube and boiled for 5 minutes for PCR. Nitrocellulose membranes were spotted with 10 µL of liquid for NCM-ELISA.

Stem sections about 20 mm long were cut and placed into tubes containing 500 µL of sterile, distilled water and allowed to ooze bacteria, or placed in individual plastic bags with 500 µL extraction buffer (TBS) with 0.2% Na_2S0_3 and macerated. Ten micro-

litres of the bacterial suspensions from the tubes and plastic bags were spotted onto nitrocellulose membrane for detection by NCM-ELISA. Ten microlitres of the bacterial suspensions from the plastic bags were spotted onto nylon membrane for the DNA probe. Five microlitres from each tube were placed in another tube and boiled for 5 minutes for detection by PCR. When stems were visibly oozing bacteria cells, the cut ends were blotted onto nylon membrane for detection by DNA probe.

Detection was by:1. NCM-ELISA technique using a polyclonal antibody to a race 3 isolate of *P. solanacearum* (CIP 308); 2. a non-radioactive, *P. solanacearum*-specific DNA probe; and 3. polymerase chain reaction (PCR) amplification with *P. solanacearum*-specific primers.

Detailed study

A sample of 30 tubers of Ndinamagara and Uganda 11 were selected at random from the store at Mwokora Seed Farm 6 weeks after harvest. Tubers of Uganda 11 from Munanira Seed Farm were collected also. Samples were prepared as follows for detection by DNA probe, PCR amplification, and NCM-ELISA.

Tubers were surface disinfested by washing in 2.5% NaOCl. Several millimeters of the stolon and heel ends were sliced off each tuber. The tuber tissue was excised from the slices, divided into halves, and placed in separate plastic bags.

One half was macerated with 250 µL sterile, distilled water, and immediately spotted onto nylon membrane (20 µL) for detection by the probe. The remaining liquid from the macerate was placed in a screw-top eppendorf tube and boiled for 5 minutes for detection with PCR. The other half was macerated with 250 µL extraction buffer (TBS) with 0.2% Na_2SO_3 and allowed to stand. Twenty microlitres of liquid from the macerate were spotted onto nitrocellulose membrane for NCM-ELISA.

Samples for PCR were kept frozen until shipped to England. Samples on nylon membranes were fixed by UV light treatment after the strands were separated with NaOH. The tests were then carried out according to standard methods. Duplicate nitrocellulose membranes were sent to England and Kenya for processing by standard NCM-ELISA procedures.

After removal of stolon and heel ends, tubers were allowed to sprout and then planted in pots. These were grown in the screenhouse at Gisozi. Plants were observed for symptoms of wilt, and progeny tubers were cut and examined for brown rot at harvest.

Samples of 100 tubers were removed at harvest from Mwokora and Munanira. These were placed in a rustic, diffused light store in Bujumbura at ambient temperature (ca. 25°C). At intervals, tubers were observed for rot.

Results

Preliminary study

Positive results were obtained by all detection methods and all sampling techniques for plants and tubers collected from the field at Mwokora (Table 1). Maceration of tissue was most effective for detection of the bacteria by NCM-ELISA and DNA probe in terms of number of positive samples and intensity of reaction.

Only the DNA probe detected bacteria in a tuber from an apparently healthy neighbour of a wilted plant. The tuber may have been latently infected and only the probe was sufficiently sensitive for detection. Further comparisons of detection methods cannot be made due to lack of conformity among samples.

In the case of apparently healthy tubers from diffused light stores, NCM-ELISA and PCR detected bacteria in basic seed tubers from Mwokora (Table 2). Data from the DNA probe clearly indicated that cross contamination had occurred.

More samples of the bacterial wilt-susceptible cultivar Uganda 11 tested positive for latent infection than the more tolerant Sangema (4 of 5 samples and 2 of 5 samples, respectively). This would indicate a latent infection rate of between 8 and 80% for Uganda 11 and between 4 and 40% for Sangema. Examination of tubers during sampling indicated that 6 of 50 (12%) Sangema tubers had slight browning of vascular bundles at the stolon end, whereas 13 of 50 (26%) Uganda 11 tubers had similar discoloration.

The pathogen was not detected in pre-basic seed from Munanira or from pre-basic seed or *in vitro*-generated mini tubers from Gisozi.

Detailed study

No latent infection of tubers from the stores at Munanira and Mwokora was detected by NCM-ELISA or by DNA probe. The pathogen was detected from stolon ends by PCR when 50 cycles were used in one sample of Ndinamagara and one sample of Uganda 11 from Mwokora, each of which cultivar had a latent infection rate of 3.3%. The tuber of Ndinamagara which tested positive failed to germinate. Wilting and rotting of progeny tubers were observed in the plant from the tuber of Uganda 11 which tested positive. All other tubers of Uganda 11 and Ndinamagara gave rise to healthy plants and progeny tubers (Table 3).

Due to lack of positive results, we could not assess the movement of bacteria between stolon and heel ends of the tuber. In the diffused light store in Bujumbura, rot was not observed in any of the tubers of Ndinamagara. Nine percent of tubers of Uganda 11 from Mwokora rotted.

Discussion

The preliminary study indicated that NCM-ELISA, non-radioactive DNA probe, and *P. solanacearum*-specific primers were able to detect the pathogen found in Burundi from tubers (latently infected as well as with brown rot) and stems. Because of bulking of tubers into samples of 10, levels of latent infection could not be determined precisely, but were greater than 4% and possibly as high as 80%. Due to variations in sampling techniques, direct comparisons of efficacy and sensitivity of detection methods could not be made. From our experience and the results of this study (Table 1), we concluded that maceration of stolon-end tissue could be used for further studies. We also believed it was important to test both stolon and heel ends as it has been observed that the location of the bacteria change during storage (El-Nashaar, pers. comm.)

The tuber-tissue-maceration technique was an effective sampling method, from a technical viewpoint. If large numbers of tubers are to be sampled, a more efficient cutting system and implement must be devised. We experienced cross contamination of DNA probe samples in the preliminary study due to the great variety of methods being employed. Sanitation practices between samples to prevent cross contamination are based on the detection technique used and the objectives of the test. For example, alcohol and/or flame sterilisation may be adequate for ELISA, which detects whole cells, but not possibly for PCR, which detects DNA. Further testing of flame sterilisation and other techniques (i.e. acid dip, rinse, alcohol flame) is needed.

A major problem encountered was starch in the sample. This can be partially overcome by allowing the sample to settle and carefully pipetting off the sample for spotting. There are methods for removing starch from membranes. These and simple cleaning procedures for PCR preps need more study.

Levels of infection at Munanira and Mwokora Seed Farms in 1992 were below the limits of detection by NCM-ELISA (10^4–10^5), DNA probe (10^5–10^6), and PCR at 35 cycles (50–100 cells, based on pure cultures). Only when the amplification by PCR was increased to 50 cycles (sensitivity of 1–10 cells, based on pure cultures) was the bacterium detectable in two

samples from Mwokora. This indicates that 1. PCR is the most sensitive method for detection; and 2. our sampling technique was able to sample for very low levels of infection.

Detection was correlated to disease in the case of Uganda 11, as the tuber found positive by PCR also produced a wilted plant and rotten progeny tubers. The tuber of Ndinamagara failed to germinate; this might be attributable to infection. However, Ndinamagara is tolerant to bacterial wilt and seldom exhibits clear symptoms of the disease.

Latent infection, measured by PCR was 3.3%, more than the 1% previously believed. However, 9% of tubers of Uganda 11 rotted when incubated in

Bujumbura at ambient temperatures. None of the tubers of Ndinamagara rotted under this treatment. It is often difficult to determine the cause of such rot by visual examination and over-estimation may result. We found it interesting that field infection, based on wilted plants rogued out, was less than 1% at both farms.

From these two studies we conclude that latent infection is still present in the potato seed from Mwokora Seed Farm and is probably higher than 1%. There is a high variability of latent infection by cultivar, season and year. Further work is under way to verify these conclusions. It is very important to determine practical levels of detection to decide if the sensitivity of PCR at 50 cycles is of relevance.

More field experience is needed to determine the best method for detection of latent infection in potato tubers on both a scientific and practical basis. For national programs in developing countries such as Burundi to utilise such upstream techniques as DNA probes and PCR amplification, they will need to collaborate with other national and international organisations and networks until national capabilities are sufficiently strengthened.

Acknowledgments

The authors wish to thank the Director General of ISABU and the Head of the National Potato Program for Burundi, Mr Ch. Muvira, for their support of this research. We also thank Mr Alphonse Rubirigi and the staff of the National Potato Program for their assistance with the sample collection.

Host Resistance

Some Characteristics Involved in Bacterial Wilt (*Pseudomonas solanacearum*) Resistance in Tomato

V. Grimault*, J. Schmit† and P. Prior*

Abstract

Attempts to control the tropical and subtropical widespread occurrence of race 1 of *Pseudomonas solanacearum* which causes bacterial wilt and severely affects vegetable crops in the lowlands throughout the world, have been hampered by the large variability of the strains and by interactions between host plants and environment. Although widely used, the physiological bases of genetic resistance are still poorly understood. To elucidate some of the mechanisms that could be involved in host-resistance, three hypotheses were examined: (i) absence of bacterial penetration; (ii) restricted colonisation of vascular tissues; and (iii) plant resistance without limitation of colonisation. *P. solanacearum* was enumerated by plate-counting at three levels (taproot, collar, and mid-stem) of resistant and susceptible tomatoes, which confirmed latent infections in symptomless plants genetically resistant to bacterial wilt, and proved that resistance does not result from absence of root penetration. The resistant plants tolerate the pathogen, i.e., the densities of bacterial cells detected at collar and middle stem did not differ significantly in symptomless resistant cultivars. The bacterial wilt resistance of 10 cultivars from the United States, Taiwan and the French West Indies was negatively correlated with the detection frequency of the pathogen in the middle stem samples. Whether colonisation could result from constitutive or from induced defence mechanisms is being investigated.

NUMEROUS reports indicate that soilborne bacterial wilt (bacterial wilt) caused by *Pseudomonas solanacearum* E. F. Smith is the most ubiquitous and damaging bacterial disease in tropical and subtropical countries (Buddenhagen 1986; French 1988; Kelman 1985; Middleton and Hayward 1990; Persley 1986). This is particularly true of race 1, which affects the development of a broad range of subsistence and cash crops (tomato, eggplant, potato, groundnuts, ginger), that are considered major crops for peri-urban diversification and low-income farming systems.

The bacterium is particularly well adapted to soil and rhizosphere survival (Granada and Sequeira 1983; Schmit et al. 1990) and enter the roots from artificial or natural openings (Kelman and Sequeira 1965; Schmit 1978). Colonisation of vascular tissues results in internal and external symptoms evolving into a total wilt of the plant (Kelman 1953).

As with other xylem-borne bacterial diseases, it is very difficult and costly to control bacterial wilt with chemicals. Therefore, reduction of the disease using farming practices needs further development and adaptation. Nevertheless, some vegetables have been grown in heavily infested soils for almost 40 years using locally appropriate resistant materials (Messiaen 1981). Breeding for resistance remains the best control strategy, even if this property may fluctuate from breeding to cropping areas, due to extreme variability and adaptation of the pathogen (Persley 1986). In the French West Indies, selection for bacterial wilt resistance on tomato and eggplant has been consistent (Anais 1986; Ano et al. 1991; Daly 1986; Denoyés 1988), and with a particular consideration of strain variation (Prior and Steva 1990; Prior et al. 1990a). At least five genes contribute to resistance in tomato (Messiaen 1981; Singh 1961), but the underlying biological mechanism has not been described. This may account for the difficulty in evaluating the effect of environmental factors on the field performance of resistant cultivars, and why bacterial wilt behaves as a persistent disease.

†Station de Pathologie Végétale, 78026, Versailles Cedex, France.

At present, most research is focused on compatible interactions between *P. solanacearum* and susceptible hosts; with noticeable recent advances in understanding of genetic determinants of pathogenicity (Allen et al. 1991; Arlat and Boucher 1988; Boucher et al. 1987; Cook and Sequeira 1991; Denny and Baek 1991; Huang et al. 1990). It is likely that modern nucleic-acid-based approaches will soon allow for the development of biological control using avirulent recombinant mutants (Trigalet and Trigalet-Démery 1990). Whatever the strategy, control of the disease can be achieved only through a better understanding of the complex interactions between *P. solanacearum*, the host genotype and the environment.

Independent reports indicated that root-knot nematodes were a major bacterial wilt predisposing factor causing breakdown in bacterial wilt field resistance (Haider et al. 1987; Napiere and Quimio 1980; Pitcher 1963; Samuel and Mathew 1983; Sellam et al. 1982). Synergism between nematodes and *P. solanacearum* on tomato was mostly associated with additional wounds caused by penetration of larvae into roots, which facilitate ingress of bacterial cells. Cadet et al. (1989) provided further evidence that *Meloidogyne arenaria* larvae hastened bacterial wilt development in a resistant cultivar, and showed that this was not caused solely by additional wounds. Larvae injuries could explain earlier wilt symptoms compared to plants without nematodes, but could not account for the variation in disease progress curves. These results suggest that plant resistance was overcome when both pathogens were developing in host tissues. These authors have considered nematode stress, i.e. development of galls on the roots (Sitaramaiah and Sinha 1985), more as a wilt triggering factor than a predisposing factor. This suggests *P. solan-acearum* should be already present in bacterial wilt resistant cultivars as a latent pathogen; and that the breakdown in resistance could result from synergism between bacterial wilt and physiological stress due to gall formation, rather than from a mere increase in available entry points.

From this observation, research programs in the French West Indies have focused on the interaction between *P. solanacearum*, host plant, and environment, with special attention to the mechanisms that are involved in tomato resistance. Two hypotheses were examined: absence of bacterial penetration in roots; and tolerance of vascular tissues to bacterial colonisation. This paper presents recent progress of the research undertaken in the French West Indies on this particular aspect of tomato resistance.

Latent Infection

As for other bacterial diseases (Aldwinckle and Preczewski 1976; Hayward 1974), observations on the ability of *P. solanacearum* to persist in plants without symptoms has been reported in some weeds (Hayward 1991), tomato lines and resistant tobacco (Digat 1966; Winstead and Kelman 1952), and peanut (Middleton and Hayward 1990). Although latent infections were well-investigated in potato tubers (Ciampi et al. 1980) and plants (Ciampi and Sequeira 1980), there have been no experimental data to explain the early and late behaviour of *P. solanacearum* occurring in resistant tomato cultivars.

Latent infection by *P. solanacearum* was assessed, using an ELISA diagnostic test on different sources of resistance in tomato (*Lycopersicon esculentum* var. *cerasiforme*): CRA 66 from the French West Indies; line Hawaii 7996 from the United States; and CRA 66 progeny (Caraïbo; Carmido, which is Caraïbo with nematode resistance *Mi* gene). The results of this experiment (Prior et al. 1990b) provided evidence that latent stem infection was frequent, and occurred from 50 to 70% in Hawaii 7996 and from 80 to 100% in Caraïbo and Carmido. The wilt resistance source CRA 66 was the exception, i.e. no plants wilted and ELISA detection was negative after root inoculation with *P. solanacearum*. This led us to consider two major components of resistance in tomato: 1. resistance may be attributed to the roots acting like a physical barrier to bacterial entrance (CRA 66); and/or 2. tolerance to *P. solanacearum* in conducting vessels (Hawaii 7996, Caraïbo and Carmido). The bacteria recovered from the stem of resistant cultivars maintained their pathogenicity on susceptible tomato.

Further studies based on ELISA diagnosis and population counts in symptomless resistant tomatoes (Grimault and Prior 1990; Grimault and Prior 1992a), confirmed previous results in resistant varieties, including the resistant genitor CRA 66. Variability of bacterial diagnosis in CRA 66 was also suspected to be associated with environmental variables. Therefore, *P. solanacearum* was capable of invading cultivars tested regardless of their susceptibility or resistance to bacterial wilt (Fig. 1). This demonstrated that the mechanism of resistance did not arise from resistance of the root to penetration by bacteria, and indicated that the resistance in tomato was related to the tolerance of conducing vessels to *P. solanacearum*.

Tomato cultivars with different levels of resistance to bacterial wilt were compared to investigate the resistance mechanism(s). Colonisation of vascular tissues by a race 1 biovar 1 isolate was studied from taproot to mid-stem by two measurements: the bacterial density in conducting vessels; and the kinetics of spatial spread. In addition, these measures were assessed in cleft-grafting experiments using susceptible and resistant tomato genotypes.

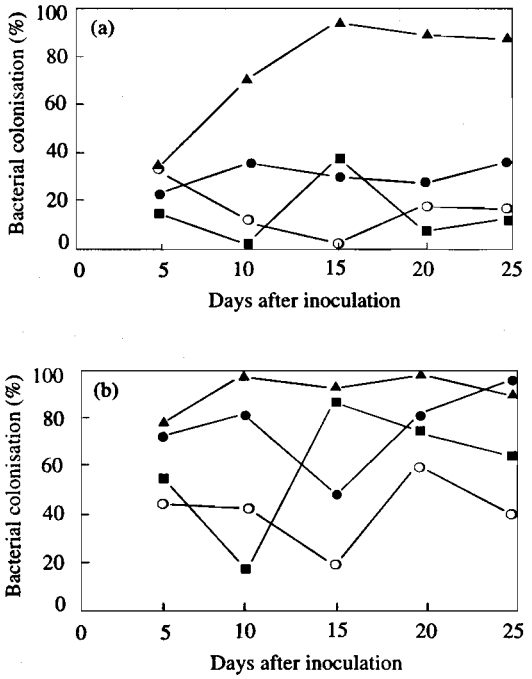

Fig. 1. Development of colonisation frequencies in tomato cultigens after inoculation with *Pseudomonas solanacearum*. Data from collar and middle stem were expressed as (number of (a) middle stem or (b) infected collar/number of corresponding infected taproots) × 100. Data resulted from positive Spiral isolations of 20 plants randomly sampled (Grimault and Prior 1992a). Floradel (S) -▲-; Caraïbo (R) -●-; CRA 66 (R) -■-; and Hawaii 7996 (R) -○-.

Bacterial Density in Conducting Vessels

Plant production and inoculation

Seeds of tomato cultivars that differed in resistance to bacterial wilt were planted into steam disinfested organic soil. Ten-day-old seedlings were transplanted into individual pots placed in an insect-proof greenhouse. *P. solanacearum* strain GMI8217, a fluidal, spontaneous mutant resistant to 200 µg/mL streptomycin and 50 µg/mL rifampicin, was selected from the previously described wild-type strain GT1 (encoded CFBP 3256) (Prior and Steva 1990; Prior et al. 1990b). Virulent, fluidal wild-type colonies were selected after 48 hours growth at 30°C on Kelman's tetrazolium chloride medium (TZC) (Kelman 1954) with antibiotics (selective medium) and suspended in sterile distilled water (SDW). These colonies were restreaked on the same medium without TZC. After 48 hours growth on selective medium free of TZC, cells were harvested by flooding the plates with SDW, and inoculum consisting of a suspension of 2×10^7 cells/mL adjusted spectophotometrically (10^7 cells/mL corresponds to an OD of 0.01 at 650 nm). Two millilitres of inoculum were poured around the base of plants and a scalpel was inserted 4–5 cm into the soil to cut the roots along one side. Symptom development was recorded every other day from 3 days to 34 days after inoculation.

Bacterial counts. Taproots were crushed and other cuttings were placed in 4 mL SDW and stored at 10°C for 15 hours to allow deposition of bacteria. Extracts were streaked on selective medium using a Spiral plater and colonies were counted after incubation of plates for 48 hours at 30°C. The limit of sensitivity for Spiral counts was 10^2 cfu/mL. Populations of *P. solanacearum* counted in tomato extracts were expressed as bacteria in cfu/g of fresh matter (cfu/g FM) and were log-transformed. A variance test was used to compare data analysis.

Whatever the susceptibility or resistance performance of cultivars, *P. solanacearum* was isolated 5 days after inoculation from all the plant stems and roots tested. There was no difference in successful infection rate, i. e., rate of positive counts in the taproot (Fig. 2).

Bacterial density increased from 10^6 to 10^8 cfu/g FM in susceptible plants from day 5 to 25 in all sites tested. Differences between resistant and susceptible cultivars occurred only at day 25, when population counts were stable in resistant taproot and collar samples (10^6 cfu/g FM on average) and decreased in mid-stem sites. These results were obtained from three resistant cultivars only, which could make questionable the validity of observations. Consequently, another experiment was undertaken (Grimault and Prior 1992b) with 10 selected resistant cultivars originating from three different geographical areas (Table 1).

Table 1. Origin and principal characteristics of selected tomato cultivars (data from Grimault and Prior 1992b).

[a]Determinate (d) or indeterminate (u) growth.
[b]The cultivar was indicated as susceptible (S), moderately resistant (MR) or resistant (R) to bacterial wilt.

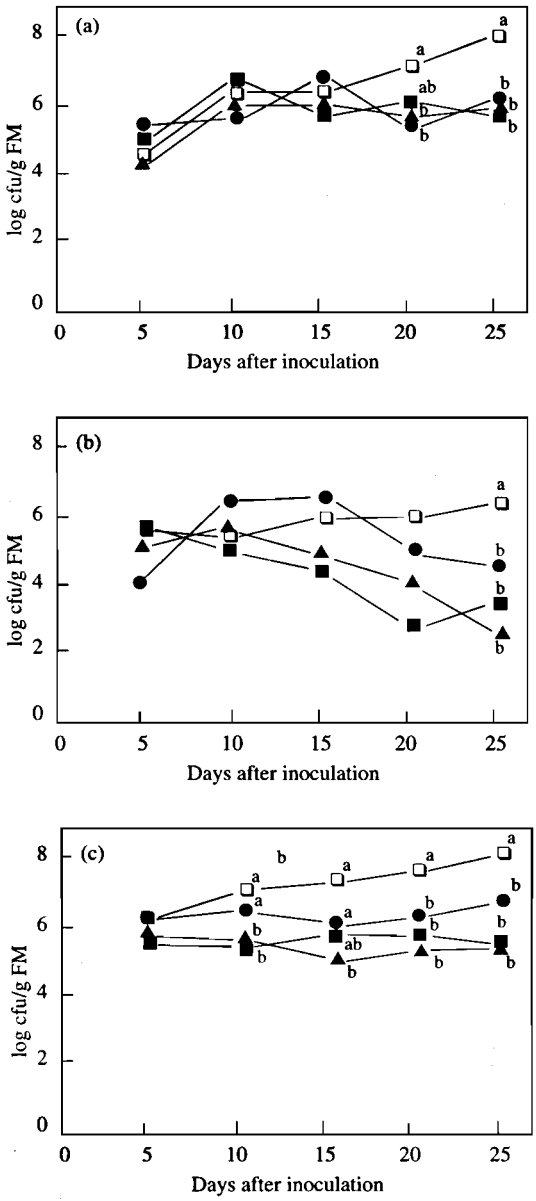

Fig. 2 Development of *P. solanacearum* populations in bacterial wilt resistant (R) and susceptible (S) tomato cultivars. Bacterial density was monitored in three sites (a, collar; b, middle stem; c, taproot) of 20 plants randomly sampled. Average bacterial density in colonised plants was expressed as average logarithm of cfu per gram of fresh matter (FM). Values without or with the same superscript were not statistically different at $P = 0.05$ level (Grimault and Prior 1992a). Floradel (S) -□-; Caraïbo (R) -●-; CRA 66 (R) -■-; and Hawaii 7996 (R) -▲-.

For these cultivars, 100 plants with 3–4 fully expanded leaves were infected and planted the next day in the field. Statistical design consisted of five randomised complete blocks, each of them containing 6 m planting rows with 20 plants of all cultivars . Ten wilted plants per cultivar were sampled and a 2 cm length fragment was cut off at midstem. Remaining symptomless plants were collected 34 days after inoculation, with a maximum of 35 plants per cultivar, and fragments were sampled at taproot, collar and midstem. All samples were tested for presence and density of *P. solanacearum*. Frequencies of wilted plants ranged from completely susceptible Floradel to highly resistant Hawaii 7996 (Fig. 3). All the cultivars were colonised by *P. solanacearum* at collar sites (from 75 to 100% positive counts). All wilted plants reached similar bacterial densities ($3.8 \times 10^9 \pm 0.4 \times 10^9$ cfu/g FM on average) at mid-stem and all symptomless plants were more heavily invaded at collar ($7.6 \times 10^6 \pm 0.6 \times 10^6$ cfu/g FM) than at mid-stem ($1.3 \times 10^4 \pm 0.6 \times 10^4$ cfu/g FM), regardless of the resistance level or the origin of the cultivar. This confirmed that latent infections are a general phenomenon in bacterial wilt resistant tomatoes. In addition, the limited variations in *P. solanacearum* counts in wilted plants, regardless of the genotype, provided evidence that the level of field resistance did not depend on a threshold of bacterial density in the stem.

Spatial Distribution

In all experiments, bacterial colonisation increased from taproot to upper sites of the stem (Grimault and

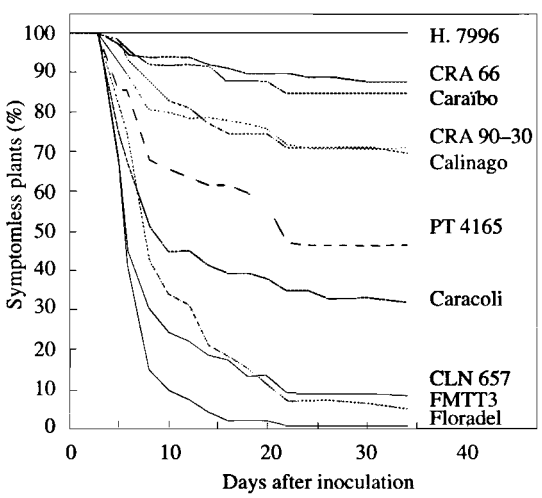

Fig. 3. Field resistance of the selected cultivars after inoculation with P. solanacearum (data from Grimault and Prior 1992b)

Prior 1992a,b; Prior et al. 1990a,b). As already noted, there was no difference in successful infections between resistant and susceptible cultivars. Differences occurred in that susceptible plants were simultaneously invaded at taproot and collar sites, but resistant ones were not. It is worthwhile noting the high, consistent, colonisation rate at mid-stem of susceptible plants (almost 100% detection) compared with the low colonisation rate in resistant cultivars (from 0 to 57% detection): the better the resistance, the lower the stem-colonisation. Because it was difficult to compare colonisation of cultivars with different levels of field resistance, i.e. symptomless plants were not of equal size, a measure (% of balanced colonisation) was elaborated. This measure consisted of a balance of the percentage of observed colonisation with the percentage of wilted and symptomless plants according to the formula: % wilted plants (100% colonisation) + [(% symptomless plants) x (% colonisation)].

Results from the 10 selected cultivars indicated a strong positive correlation between succesful infections at mid-stem and bacterial wilt frequencies (Fig. 4). This result provides the first evidence that resistant cultivars tolerate consistently high *P. solanacearum* concentrations, while restricting the spatial colonisation in the stem.

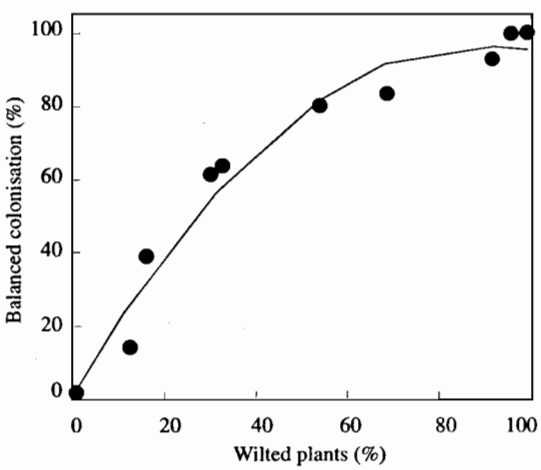

Fig. 4. Correlation between bacterial spread and wilt frequencies within selected cultivars. To compare all the cultivars, the bacterial colonisation at mid-stem was expressed with consideration to bacterial wilt frequencies according to the formula: %wilted plants (100% colonisation) + [(% symptomless plants x % colonisation)]. A strong positive correlation ($y = -0.012\ x^2 + 2.14\ x + 1.2$; $r^2=0.97$) occurred between bacterial colonisation and bacterial wilt frequencies (data from Grimault and Prior, 1992b).

Cleft-grafting

Although time-consuming and an out-of-date method, grafting a susceptible genotype with local adaptation onto a wilt resistant eggplant (*Solanum melongena* L, *S. torvum* Sw., and *S. æthiopicum* L.) or tomato root-stock, provides a useful alternative to avoid bacterial wilt in situations of high infestation and when resistant tomato cultivars are not available. Attention to latent infection and tolerance to *P. solanacearum*, which have been recently observed in tomato, provides a new approach in understanding the mechanism of resistance through grafting.

Two tomato cultivars Floradel (Flo) and Caraibo (Car), were selected for susceptibility and resistance to bacterial wilt, respectively. Grafting was performed with 4 week-old root-stocks and 3 week-old scions. Root-stocks were topped above the second leaf, and the foliar surface of scions was reduced by cutting leaves by half. Grafts were bound using a parafilm sheet and plants were protected in a shadehouse (8–10 days) until shoot was well established. Scion–root-stock grafting experimentation consisted of 110 Flo/Car, 40 Car/Flo, 20 Flo/Flo and 20 Car–Car. All homogeneous plants (80% size) were inoculated 10 days after grafting. Alcohol-disinfected stem cuttings (2 cm) were sampled 3 weeks after inoculation at collar, below and above graft scar and 10 cm above graft scar.

Invasiveness of *P. solanacearum* was assessed in plants resulting from different scion–root-stock combinations. Severity of bacterial wilt in plants with susceptible root-stocks was 50%, whereas no plant wilted when using resistant root-stock. Bacterial density and spread in grafted plants are presented in Table 2. There were no significant differences in detection frequencies of *P. solanacearum* at collar sites of resistant and susceptible root-stocks. This was a confirmation that resistance in tomato did not result from unsuccessful infection. Resistant and susceptible scions were invaded at similar rates and densities when grafted on the same root-stock. Colonisation rates above graft-scars decreased from 80–100% to 20–40% and bacterial densities from nearly 3 to 2 log units when scions grafted onto susceptible root-stocks were compared with the same scions grafted onto resistant root-stocks (Table 2). These results provided further evidence that bacterial wilt resistance in tomato is associated with the ability of the plant to restrict bacterial invasiveness.

Prospects for Mechanisms of Plant Resistance

The restriction of pathogen spread in conducting vessels has been reported as a wilt resistance mechanism in various vascular plant diseases

Table 2. Comparison of *P. solanacearum* distribution inside plants that had different combinations of cleft-grafts between susceptible (Floradel) and resistant (Caraïbo) tomato genotypes (data from Grimault and Prior 1992b).

	Log cfu/g FM[a]				% colonisation			
Graft[b]	Collar	< GS[c]	> GS	10 cm> GS	Collar	<GS	>GS	10 cm> GS
Flo/Car	5.02 a	3.94 a	3.53 a	3.56 a	95.5	68.5	39.3	20.2
Car/Car	5.22 a	4.42 a	4.09 ab	2.61 a	100	64.3	35.7	28.6

(Beckman 1987; Beckman et al. 1972; Elgersma et al. 1972). Different hypotheses have accounted for resistance, including differences in vascular anatomy and/or the number of xylem vessels free of pathogens, and variations in tyloses and accumulation of amorphous material (Beckman 1987). Investigations of colonisation of *P. solanacearum* in susceptible hosts, have included studies on: bacterial penetration (Schmit 1978); mode of colonisation and mechanical plugging of water-conducting vessels by bacterial cells (Petrolini et al. 1986); production and nature (paired or impaired) of complex exopolysaccharides *in planta* (Orgambidet et al. 1991); and induction of tyloses (Lin and Stevenson 1979; Wallis and Truter 1978).

In regard to the high density of bacterial cells counted in the stems of symptomless resistant plants, further research is needed to determine if the restriction of bacterial spread in stem tissues results from a constitutive or from an induced defence mechanism. The current investigations on the incompatible interactions between virulent strains and resistant host are likely to contribute to the answer to that question.

Also, the past and recent attempts to induce resistance in susceptible hosts (Prior and Béramis 1990; Sequeira et al. 1977), and to protect susceptible hosts with spontaneous (McLaughlin and Sequeira 1988; McLaughlin et al. 1990) or recombinant avirulent mutants (Trigalet and Démery 1986; Trigalet and Trigalet-Démery 1990) highlight some aspects of resistance mechanisms. Such reexamination may explain, to some extent, why attempts to select stable resistance in tomato were unsuccessful (Hayward 1991), compared with peanuts and tobacco (Thurston 1976).

Breeding for More Stable Resistance

Buddenhagen (1986) stated, 'if resistance is insufficient in a crop rapidly breedable (such as tomatoes, chillies, etc.), one should ask why?' Polygenic resistance of tomato has been reported to be overcome (Messiaen 1981; Thurston 1976; Singh 1961), and was generally thought to be caused by strain variations and/or to be a consequence of the interactions between host genotype, pathogen, and environment (Hayward 1991). The ability of *P. solanacearum* to establish symptomless infections in Hawaii 7996, which was reported to express a complete, dominant resistance simply inherited (Messiaen et al. 1991), supports this latter view. The positive detection of bacterial wilt in nine tomato cultivars with different levels of resistance (Grimault and Prior 1992b) indicates that symptomless colonisation in resistant tomatoes is of general occurrence. This was recently confirmed (J.C. Girard, CIRAD-IRAT, pers. comm.) in another area, Réunion Island, on several tomato cultivars. The performance of the different resistant cultivars tested in Guadeloupe corresponded to the expected level of resistance, except for FMTT 3 and CLN 657 from Taiwan (AVRDC). Resistance was not expressed in those cultivars but it was in PT 4165 which is considered to have the same origin. This result suggests that the level of resistance of a cultivar may depend not only on pathogenicity of local strains, but also on the influence of the environment.

The general criterion used in breeding for bacterial wilt resistance in tomatoes has been extent of wilt. We propose to introduce in breeding programs a complementary measure based on the extent of colonisation by *P. solanacearum* in the mid-stem. Breeding in the French West Indies will apply this strategy to evaluate field resistance in tomato lines and progenies.

We postulate that stable resistance will be selected in the future through multilocational collaborative evaluations of bacterial colonisation. This could help to determine if variations in this measure of resistance could occur within a cultivar, in relation to strain aggressiveness and/or environmental variables.

Acknowledgments

Thanks go to G. Anais and J. C. Girard for providing tomato cultivars. We are grateful to J. Fournet and J. G. Elphinstone for valuable discussions and advice during the writing of this paper, and to A. Trigalet for providing *P. solanacearum* strain 8217.

Comparison of Inoculation Techniques for Screening Tomato Genotypes for Bacterial Wilt Resistance

G.C. Somodi, J.B. Jones and J.W. Scott*

Abstract

Several screening techniques were compared for differentiating tomato genotypes which are susceptible or resistant to bacterial wilt. The procedure which appeared most effective involved pouring inoculum over plant roots in Todd planter flats and transplanting 3 days later to the field. Wounding the roots with a knife during the inoculation procedure did not influence disease development. This procedure was extremely effective except during the colder months when resistant plants could not be effectively discerned from susceptible genotypes. Dipping roots in inoculum or planting diseased susceptible plants adjacent to or alternately with noninoculated test plants resulted in significantly fewer susceptible tomato plants developing bacterial wilt symptoms than treatments in which inoculum was poured over the root system prior to transplanting. In Florida, where naturally infested soil may not be available for screening tomato genotypes, pouring 5 mL of a suspension containing 10^7 cfu/mL of *P. solanacearum* over the roots of test plants approximately 3 days prior to transplanting, provides an adequate method for screening.

BACTERIAL wilt of tomato (*Lycopersicon esculentum* Mill.), incited by *Pseudomonas solanacearum* E. F. Smith, is a devastating disease in tropical and subtropical regions of the world. The disease has limited both commercial and home tomato production. Resistance to bacterial wilt in tomato genotypes has been reported from several sources (Acosta et al. 1964; Atabug and San Juan1981; Peterson et al. 1983; Sonoda and Augustine 1978; Winstead and Kelman 1952); however, incorporation of resistance into material with good horticultural characteristics has been very difficult (Thurston 1976).

Selection of resistant material depends on the bacterial strain variation (Prior et al. 1990), genetic variability of the plant and reproducibility of the inoculation technique. Various techniques have been used for screening genotypes with high levels of resistance to bacterial wilt. Winstead and Kelman (1952) distinguished bacterial wilt resistant genotypes from susceptible genotypes by pouring the inoculum around the base of the plant and then inserting a knife to cut the roots. They compared this with inoculating the stems and determined the stem injection to be too severe. However, stem inoculation has been used successfully for differential determinations of bacterial wilt susceptibility (Krausz and Thurston 1975; Mew and Ho 1977). Other techniques which have been used to screen for resistance include: screening in naturally infested soil (Peterson et al. 1983; Sonoda and Augustine 1978); dipping roots in a bacterial suspension (Winstead and Kelman 1952); petiole inoculation (Atabug and San Juan 1981); soil inoculations and dipping seedling roots into inoculum (Acosta et al. 1964); and inoculating susceptible plants and placing them adjacent to test plants (Narayanankutty and Peter 1986). Correctly identifying material with moderate levels of resistance or breeding for resistance, from genetic material with polygenic resistance, requires that a technique be selected that is not too severe.

This paper compares a number of techniques for differentiating between bacterial wilt resistant and susceptible genotypes. Reproducibility of these techniques for identifying resistant material and some of the problems associated with screening for resistance were also studied.

*University of Florida, Gulf Coast Research & Education Center, 5007 60th Street, E. Bradenton, FL 34203, USA.

Materials and Methods

Bacterial strains and inoculum production

All strains used in this study were isolated from tomatoes in Florida except for one supplied by S. M. McCarter (Department of Plant Pathology, University of Georgia, Athens, Georgia, USA). Strains were grown on a tetrazolium medium (Kelman 1954). Virulent colonies were selected and streaked for inoculum onto nutrient-yeast-dextrose agar and incubated for 48 hours at 28°C. Bacterial growth was gently removed from the agar surface and suspended in 0.01 M $MgSO_4 \cdot 7H_2O$ to a concentration of 3×10^8 cfu/mL by adjusting the suspension to 0.15 O.D. at 590 nm with a spectrophotometer. The suspension was diluted to the desired concentration in 0.01 M $MgSO_4 \cdot 7H_2O$.

Comparison of inoculum concentration and inoculation techniques for bacterial wilt development in the field

Seeds of the tomato genotypes Hawaii 7997 (resistant), Walter (susceptible), and MH1 (susceptible) were sown in Black Beauty spent coal (Reed Minerals Div., Highland, IN) in wooden flats and covered with a layer of vermiculite. Ten days after sowing, seedlings were transplanted individually to planter flats (Todd Model 51). Transplants were grown for 30 days and then inoculated by one of the following methods: (a) 5 mL of a bacterial suspension consisting of 10^7 cfu/mL were applied to the surface of each cell; (b) 5 mL of a bacterial suspension consisting of 10^8 cfu/mL were applied to the surface of each cell; (c) same as treatment 1 except that the roots of each plant were damaged by inserting the blade of a knife prior to inoculation to the bottom of each cell; 4. same as treatment 2 except that the roots of each plant were damaged by inserting the blade of a knife prior to inoculation to the bottom of each cell; 5. MH1 plants were inoculated as in treatment 1 and used as a source of inoculum for Hawaii 7997 and Walter plants in the field by planting inoculated plants adjacent to healthy plants in the same hole; or 6. MH1 plants were inoculated as in treatment 2 and used as a source of inoculum for Hawaii 7997 and Walter plants in the field by planting inoculated plants adjacent to healthy plants in the same hole.

Transplants were set in the field in plastic-mulched raised beds fumigated with methyl bromide:chloropicrin (67%:33%). Fertilizer and pesticides were applied according to standard recommendations. Water was applied by seepage irrigation. The experiment was set up as a randomised complete block design consisting of four blocks. Each plot consisted of 10 plants spaced 45 cm apart. Two months after transplanting to the field, the percentage of healthy plants was determined.

Seedling inoculation

Seedlings were sown in spent coal as previously described. Roots of 10-day-old seedlings were dipped in one of three concentrations of *P. solanacearum* inoculum (10^8, 10^7, or 10^6 cfu/mL). Inoculated seedlings were transplanted to Todd planter flats and placed in Percival growth chambers at one of four temperatures (20, 25, 30, or 35°C). Symptom development was determined 11 days after inoculation.

Effect of inoculum concentration on differential reaction to bacterial wilt

Four-week-old Hawaii 7997 and Walter plants grown in Todd planter flats were inoculated by pouring 5 mL of inoculum (10^8, 10^7, or 10^6 cfu/mL) of *P. solanacearum* around the base of the plant. The plants were transplanted to 10 cm pots and grown at 30°C. Twenty-four days after inoculation, plants were rated for bacterial wilt symptoms.

Results and Discussion

In the spring 1990 field study, Hawaii 7997 had significantly fewer plants showing bacterial wilt symptoms than the susceptible cultivar, Walter (Table 1). This was evident throughout the experiment. Inoculum concentration did not have any effect on bacterial wilt except early in the experiment with the higher concentration causing significantly more visible disease development than the lower concentration. There was no increased disease development when plant roots were wounded prior to inoculation compared with plants inoculated without wounding. A likely explanation for

Table 1. The effect of concentration of *Pseudomonas solanacearum* and inoculation technique on percentage survival of Hawaii 7997 (resistant) and Walter (susceptible) plants in the field.

	Survival (%)		
	March 22	April 26	June 6
Cultigen			
Hawaii 7997	91.9a[a]	91.2a	93.1a
Walter	18.8b	1.3b	0.0b
Bacterial concentration[b]			
10^7	64.4a	47.4a	47.4a
10^8	46.3b	45.0a	45.6a
Inoculation technique			
Wounding	55.0a	46.2a	46.2a
No wounding	55.6a	46.3a	46.2

[a]Numbers in the same column followed by the same letter are not significantly different at P = 0.05.

[b]For bacterial concentration and inoculation technique the values represent the average of the two genotypes.

this may be that root wounding occurs when the plants are removed from the flats at the time of transplanting. In comparing the three inoculation methods in which the plants were inoculated directly by placing the inoculum on the roots (wounded or nonwounded) or by placing inoculated susceptible plants adjacent to healthy resistant and susceptible plants, pouring the inoculum over wounded or unwounded roots was more effective in differentiating the susceptible plants from the resistant ones (Table 2). No interaction existed between inoculum concentration and genotype. The first two techniques eliminated all susceptible plants, whereas the adjacent technique eliminated only approximately 75 percent of the susceptible plants. When inoculum was poured over the roots of plants in the field, disease development was very low on both susceptible and resistant genotypes (data not shown).

Table 2. Effect of inoculation method using *Pseudomonas solanacearum* on survival of tomato plants.

Inoculation technique	Survival (%)	
	Walter	Hawaii 7997
Roots-wounded[a]	0.0a[b]	92.4a
Roots-not wounded[c]	0.0a	93.8a
Adjacent[d]	23.8b	97.5a

[a]Tomato plants were inoculated by wounding the root system and pouring the inoculum directly over the roots.

[b]Numbers in the same column followed by the same letter are not significantly different at $P = 0.05$.

[c]Tomato plants were inoculated by adding inoculum directly to the roots.

[d]Tomato plants were inoculated by placing diseased susceptible plants adjacent to test plants.

Growth room studies for screening for resistance to bacterial wilt produced variable results (Table 3). In the first experiment the two higher concentrations differentiated between the resistant and susceptible genotypes. In the second experiment none of the concentrations was useful for differentiating between the two genotypes. In screening tests, results similar to the second experiment do not commonly occur and it may be the result of the plants being grown under relatively cool conditions before inoculation. In that particular experiment the average low temperature during plant growth prior to inoculation was 3.3°C lower than normal. In an experiment (data not shown) conducted in February 1990, most Hawaii 7997 plants were affected at 10^8 cfu/mL. Again, the temperature was quite low during the growing of the plants prior to inoculation.

In experiments where seedlings were uprooted and roots were inoculated by dipping in bacterial suspensions of various concentrations, variable results were

MH1	0	75	88	25	100	100

[a]Value represents percentage of plants out of eight which were wilted or dead.

associated with the two experiments (Table 4). There was no clear indication that resistant plants could be distinguished from susceptible ones. Plant age may be responsible for the lack of resistance in Hawaii 7997. Winstead and Kelman (1952) observed that younger plants are more susceptible to the bacterial wilt organism. Plants in our study were considerably younger than those Winstead and Kelman tested and in turn may be less resistant to bacterial wilt than what they observed.

Although seedling inoculation procedures can work effectively if conditions remain constant, screening in naturally affected soil appears to offer more promise for advancing breeding material. Peterson et al. (1983) and Sonoda and Augustine (1978) were successful in selecting for resistant genotypes. Furthermore, Peterson et al. (1983) developed the tomato cultivar, Scorpio, a moderately large sized fruit which has excellent resistance to biovar 3 strains in Australia.

The complexity of the resistance, coupled with what appears to be a close linkage with fruit size, necessitates that careful selection be used. Hawaii 7997, which apparently derives its resistance from *L. pimpinellifolium* PI 127805A, appears to have a number of genes associated with resistance (Acosta et al. 1964). Acosta et al. (1964) noted that fruit size has continued to be an elusive goal in selecting for bacterial wilt resistance. Walter (1967) also referred to the difficulties of incorporating bacterial wilt resistance into plant material with large fruit. Screening plant material in non-field conditions may result in loss of material with intermediate levels and in some cases high levels of resistance. This may be especially true in Florida where temperature fluctuations between summer and winter can be extremely high and appear to result in erratic growth room screening. Evaluations in naturally infested soils appear to offer advantages that greenhouse or growth room conditions do not. However, where naturally infested soil is not available, progress has been made by pouring inoculum over the roots of transplants in flats and transplanting to the field several days later.

Table 4. The effect of inoculum concentration and incubation temperature on bacterial wilt of a resistant (Hawaii 7997) and a susceptible (MH1) genotype when roots were inoculated by dipping in a suspension of *Pseudomonas solanacearum*.

Breeding for Resistance to Bacterial Wilt of Tomato in Queensland, Australia

J.A. Barnes and L. Vawdrey*

Abstract

Past and present breeding programs for bacterial wilt resistance in tomatoes are discussed. Results have been limited by the lack of high-temperature resistance. Selections in each succeeding generation have been made in the field. The field sites used have been uniform and severely infested with the bacterial wilt organism. During the past year the resistance of field selections has been confirmed under controlled temperatures using a glasshouse seedling screening technique. In the present program Rodade was used as the source of bacterial wilt resistance. Seventh generation progeny are currently being assessed. The seedling screening method has confirmed that this resistance will breakdown above 32°C. However, released cultivars would have potential for at least 50% of Bundaberg's production season.

BACTERIAL wilt (*Pseudomonas solanacearum*) is the most important bacterial disease of tomatoes in Queensland, Australia and has been a limiting factor in tomato production in the wet coastal areas of the State. Resistant cultivars are necessary for the control of bacterial wilt.

The North Carolina wilt-resistant cultivars, Venus and Saturn, did not withstand the strains of the pathogen present in Queensland. The Philippine line VC9-1 was highly resistant to local strains of *P. solanacearum* and was crossed with Floradel. The bacterial wilt resistant cultivar Scorpio was released at the F10 generation (Petersen et al. 1983). Scorpio was grown commercially in wilt-infested soil in southeast Queensland for a number of years. Losses were minimal except under conditions of very high temperatures. Mew and Ho (1977) showed the resistance in the parent VC9-1 was unstable at soil temperatures above 32°C. Scorpio plants had a high mortality rate at soil temperatures above 32°C.

Two further cultivars were released from this program. Redlands Summertaste is the hybrid between Scorpio and Flora-Dade (Herrington and Saranah 1985). Redlander is an inbred derived from Redlands Summertaste (Herrington and Brown 1988).

*Queensland Department of Primary Industries, Bundaberg Research Station, MS108, Ashfield Road, Bundaberg 4670, Queensland, Australia

These cultivars were satifactory for districts that were only short distances from markets. However, during the past 10 years the Bundaberg district has emerged as the major tomato production area of Queensland. Tomatoes are supplied to all capital cities of Australia. Bacterial wilt also became a problem during this time. Existing cultivars were not suitable for commercial production at Bundaberg.

Rodade, a cultivar bred in South Africa with resistance to South African strains of *P. solanacearum* (Bosch et al. 1985), showed good tolerance to the strains present at Bundaberg. Rodade has small, good quality fruit (100 g) and was used as a parent in a new breeding program begun in 1989 with the aim of transferring the resistance and fruit quality of Rodade into a larger fruited cultivar (150–170 g). Seventh generation progeny are currently being field-evaluated.

Resistance to bacterial wilt was assessed by planting five-to six-week-old container grown seedlings into a uniform and severely infected site on a grower's property. In each planting the entire site was interplanted with susceptible indicator plants (cv. Flora-Dade). The site was mapped for disease incidence in 1990 and showed 96% indicator plant death. A suspension of *P. solanacearum* was pumped through the drip irrigation to further infect the site. Indicator plant survival has been almost zero in the later plantings.

The development of a seedling screening technique has allowed for the field selections to be tested under controlled glasshouse conditions. The method uses heated seedling propagation trays filled with sterilised potting mix. Five-week-old seedlings are root dipped in a known concentration of the bacterium, planted into the trays and rated for disease incidence over a two-week period. The method allows the selections to be screened for disease incidence at different temperatures.

Results from the initial screening indicate that the bacterial wilt resistance of cultivars resulting from this new breeding program will not be sufficient at soil temperatures above 32°C. A source with resistance to high temperatures will be necessary for incorporation into the program. However, cultivars containing the resistance from Rodade will be satisfactory for at least four months or 50% of the production season at Bundaberg.

Testing Tomato Genotypes and Breeding for Resistance to Bacterial Wilt in Florida

J.W. Scott, G.C. Somodi and J.B. Jones*

Abstract

Hawaii 7997 tomato plants had greater resistance to bacterial wilt than CRA 66 and PI 126408 in only one of six seasons. All three of these genotypes had reasonably good resistance, generally greater than that of Hawaii 7998. Other genotypes with good resistance (> 80% healthy plants) in 1992 testing were Hawaii 7996, GA 1565, GA 1405, and GA 219 (derived from PI 126408). Bacterial wilt resistant varieties with intermediate (40-80% healthy) resistance were Caribe, Calingo, and Caricoli. Rodade was susceptible (12.5% healthy). Accessions GA 1095, 84 BWR, and IHR 663 had intermediate resistance. Breeding lines derived from Hawaii 7997, GA 1565, and GA 219 had resistances comparable to their respective resistant parents in a spring experiment, but only the breeding line derived from GA 219 was statistically as resistant as its parent in a summer experiment. Hybrids with Hawaii 7997, Hawaii 7998, GA 1565, and GA 219 as parents tended to be more resistant than the susceptible control line in two seasons of testing. Collectively, hybrids were skewed toward resistance, and genetic control based on hybrid results favours incomplete dominant gene action for these four resistant sources.

BACTERIAL wilt of tomato (*Lycopersicon esculentum* Mill.), incited by *Pseudomonas solanacearum* E.F. Smith, is a devastating disease in many humid tropical regions (Yang 1979). Developing commercially acceptable, resistant varieties has been a goal of many breeding programs (Denoyes and Aviers 1989; Opena et al. 1989; Tikoo et al. 1989). Although several resistant varieties have been developed, the resistance often breaks down in other growing regions. This is likely due to different races or biovars of the pathogen and/or inadequacy of the resistance under environmental conditions favourable to the pathogen.

In Florida, Sonoda and Augustine (1978) found Hawaii 7997, CRA 66, and PI 126408 to be among the best resistant sources that they tested. Since that time we have tested some additional genotypes.

Genetic information regarding control of resistance in several tomato genotypes has been reported. Tikoo et al. (1983) found resistance from CRA 66 to be primarily recessive. Scott et al. (1988), found resistance from Hawaii 7998 was largely controlled by a single dominant gene but other genes were also considered important. Acosta et al. (1964) found resistance from PI 270805A, the progenitor of Hawaii 7996, 7997, and 7998, to be partially dominant early in the season. The hybrid resistance broke down more than PI 270805A late in the season. The objectives of this paper are to update the information available on resistant sources to bacterial wilt that are most effective under conditions at Bradenton, Florida, and to give some genetic information based on hybrid performance for several resistant sources. Optimal breeding approaches are precluded by the lack of a coordinated worldwide effort to test resistant sources, as was suggested some time ago (Thurston 1976). This concept will be discussed anew.

*University of Florida, IFAS, Gulf Coast Research and Education Center, 5007 60th Street East, Bradenton, FL 34203, USA

Materials and Method

Field studies over seven seasons from 1989 to 1992, compared bacterial wilt incidence for three resistant genotypes (Hawaii 7997, CRA 66, and PI 126408) identified in Florida by Sonoda et al. (1979); Hawaii 7998, a bacterial wilt tolerant accession with bacterial spot (*Xanthomonas campestris* pv. *vesicatoria*) resistance (Scott et al. 1988); and susceptible controls Fla. MH1 or Horizon. Seed for each genotype was sown in sterilised wood flats containing an inert processed product of spent coal, and lightly covered with coarse vermiculite. When seedlings germinated

and cotyledons were expanded, they were transplanted into Todd (R) planter flats with 3.8 × 3.8 × 6.3 cm cells containing vermiculite and Canadian peat (1:1, v:v) amended with superphosphate, dolomite and hydrated lime (6.7, 3.3 and 1.7 kg/m^3, respectively). Thirty days later, plants were inoculated with 5 mL of 10^7 cfu/mL of *Pseudomonas solanacearum* dispensed at the base of each plant as described by Somodi et al. in a paper elsewhere in these proceedings comparing inoculation technique. Inoculum was prepared by selecting virulent colonies of local strains of the bacterium grown on tetrazolium chloride medium (Kelman 1954) and transferring to nutrient-yeast-dextrose agar for 48 hours at 28°C. The bacteria were washed from the plates, suspended in 0.01 M $MgSO_4$ and adjusted to 10^7 cfu/mL. Three days after inoculation, plants were transplanted into raised beds of EauGallie fine sand which were 20 cm high and 84 cm across. The beds were 152 cm apart and were covered with plastic mulch. At least two weeks before planting the beds were fumigated with methylbromide:chloropicrin (67:33%). Standard fertiliser and pesticide practices were used. Irrigation was seepage from ditches between every six beds. Plants were staked and tied. A completely randomised design was used with two replications of 10 plants in summer and fall, 1990; three replications of 10 plants in summer 1989, fall 1991, and summer 1992A; four replications of 10 plants in fall 1989; and five replications of 5 plants in spring 1990. There were 46 cm between plants in each row. The spring planting was transplanted in late February 1990, the three summer experiments were transplanted in early July and the three fall experiments were transplanted in late August. Plants were rated weekly for bacterial wilt symptoms, which ranged from wilted leaves to death. Approximately 3.5 months after field setting, the percentage of healthy plants was calculated and transformed to the square root of the arcsine for analysis of variance.

In a second summer 1992 experiment, 23 genotypes were compared for bacterial wilt resistance. These consisted of: 11 genetic resistant accessions, 5 varieties with reported resistance; 4 resistant Florida breeding lines chosen because of their high resistance levels during earlier testing; 1 resistant × susceptible hybrid; and 2 susceptible controls. Seedlings were grown and inoculated as previously described. Field transplanting (6 July 1992) was in a randomised block design with 4 blocks of 10 plants per plot. Plants were rated weekly for disease symptoms. Data are presented for readings made on 8 September 1992, 57 days after transplanting (DAT). All other growing systems and data analysis were described earlier.

In spring 1992, an experiment compared four of the more resistant breeding lines to Hawaii 7997, Hawaii 7998, CRA 66, PI 126408, GA 219, and GA 1565. 'Florida MH1' was used as a susceptible control. These 10 genotypes were grown in a randomised block design with 3 blocks of 8 plants per plot. Plants were transplanted to the field on 28 February 1992 and disease incidence data were taken on 10 June 1992 (103 DAT). Growing conditions, inoculation procedure, and data analysis were as described earlier.

In 1990, spring and summer experiments compared bacterial wilt resistant sources and resistant × susceptible hybrids derived from several of these sources. The inbreds tested were: Hawaii 7997; Hawaii 7998; GA 1565; GA 219; Fla 7421 (breeding line derived from Hawaii 7997); CRA 66; GA 1405; GA 1095; and 84 BWR. The first four inbreds above were each crossed with a susceptible inbred and the resultant hybrids were tested. Fla 7421 was crossed with four susceptible inbreds and these four hybrids were tested. Horizon was the susceptible control. In the spring, experiment plants were field set on 27 February 1990, and rated weekly for bacterial wilt. Data are presented for the last day: 7 June 1990 (100 DAT). In the summer experiment, plants were transplanted to the field on 24 July 1990. Data were recorded weekly for bacterial wilt symptoms and the data presented was taken on 13 September 1990 (51 DAT). Both experiments were randomised block designs with three blocks and seven plants per plot. Greenhouse growing, inoculation, field growing, and data analysis were all as described previously.

Temperatures in the spring experiments typically ranged from 21–23°/12–24°C day/night in February and March, respectively, gradually increasing to about 33/22°C day/night in June. Temperatures of the summer experiments ranged from 33–35°/22–24°C day/night from July through September. Temperatures of the fall experiments started at 33–35°/22–24°C day/night in August, gradually decreasing to 24–27°/12–15°C day/night in early December. Most precipitation occurs in the summer months (June through September) while other months tend to be dry.

Results and Discussion

Hawaii 7997, Hawaii 7998, CRA 66 and PI 126408 were tested over 6 or 7 seasons (Table 1). Hawaii 7997 was most consistent in resistance, ranging from 61–100% healthy. Except for fall 1989, Hawaii 7997 did not have significantly greater resistance than CRA 66 (66–97% healthy) or PI 126408 (45–97% healthy). Hawaii 7998 ranged from 30–80% healthy plants and tended to be less resistant than Hawaii 7997, CRA 66, and PI 126408. Susceptible controls were always more susceptible than the resistant lines and exhibited 0–15% healthy plants over the 6 seasons they were tested.

Table 1. Bacterial wilt incidence for tomato genotypes grown over several seasons in the field.

Genotype	Healthy plants (%)						
	Summer 1989	Fall 1989	Spring 1990	Summer 1990	Fall 1990	Fall 1991	Summer 1992A
Hawaii 7997	61.1a[a]	89.4a	100.0a	90.0a	80.0a	65.5a	100.0a
Hawaii 7998	47.9a	30.0c	–	80.0 a	35.0ab	49.0b	73.3b
CRA 66	69.4a	65.9b	88.0a	(40.0)[b]	85.0a	77.4a	96.7a

[b]Data from one replication only, not analysed statistically.

In the second summer 1992 experiment, there were no significant differences among the four resistant accessions listed above (Table 2). Also, among the most resistant genotypes were Hawaii 7996, GA 1565, GA 1405, and GA 219. Other resistant accessions tended to be more intermediate in resistance, although differences were not significant with at least some of the most resistant group mentioned above. Neither did several of the 'intermediate group' have significantly less disease than the susceptible controls Sunny or Florida 7060, which had 26.7 and 30% healthy plants, respectively. Caribe had the highest percentage of healthy plants (70%) of the varieties tested, but it was not significantly different from Calinago, Caracoli, and Rotam-2. Rodade had the lowest percentage of healthy plants and was statistically similar only to the two susceptible controls. Fla 7421 and Fla 7342, both derived from Hawaii 7997, and Fla 220-1, derived from GA 1565, had a lower percentage of healthy plants than did their respective parents, whereas Fla 228-2 was not

In general, hybrids with Hawaii 7997, Hawaii 7998, GA 1565, GA 219, and Fla 7421 had greater resistance than the susceptible control, Horizon (Table 4). In summer 1990, the Walter × Hawaii 7997 hybrid was statistically similar in resistance to Hawaii 7997 and significantly greater than Horizon. Although Hawaii 7997 was not tested in the spring 1990, the Hawaii 7997 × Walter hybrid was more resistant than Horizon. Results with Hawaii 7998 and its hybrid were similar to those for Hawaii 7997, except that the resistance of Hawaii 7998 was lower than expected in summer 1990. The results support the contention that bacterial wilt resistance from Hawaii 7998 is controlled by a high degree of dominance for genetic control of resistance, which agrees with our previous finding (Scott et al. 1988). Earlier work by Acosta et al. (1964), who studied inheritance of Hawaii 7998's progenitor PI 127805A, indicated resistance was incompletely dominant, with F_1 resistance becoming less effective than homozygous resistance late in the season. A high degree of dominance for resistance was also seen in hybrids between GA 1565, GA 219 and susceptible genotypes (Table 4). All four hybrids derived from Fla 7421 had significantly greater resistance than Horizon in the spring experiment. In the summer experiment, two hybrids were not significantly different from Fla 7421 and had greater resistance than Horizon, while the other two hybrids were not significantly different from Horizon. Thus, if using any of these resistant sources, a hybrid breeding approach using one resistant parent may be of some value. This might be the best way to obtain adequate horticultural quality in the short term. Homozygous resistance would be better in the long term.

The breeding lines tested (Tables 2–3) were chosen because they were among the most resistant from a large pool of breeding lines previously inoculated. However, it has been difficult to obtain breeding lines as resistant as the source from which they were derived. The reason for this is not clear. Since most plants are killed by our inoculation technique before flowering, it cannot be related to a fruit load effect. However, the recurrent parents utilised are generally large fruited and determinate. Associations between bacterial wilt resistance and small fruit size and indeterminate plant habit have been reported for PI 127805A, the progenitor of the Hawaiian lines in this study (Acosta et al. 1964). Even though breeding advances for fruit size in determinate plant habits have been made, some resistant genetic factors may still be lacking due to linkage. Hawaii 7996 is determinate and had very good resistance in summer 1992. Thus, a linkage between indeterminate plant habit and resistance would be broken with this line. This does not preclude such a linkage is still in Hawaii 7997 or could be in GA 1565 or GA 219. Critical testing of possible linkages has not been done.

Fla 7421 is a determinate, heat-tolerant breeding line with medium to large fruit. It has had a better level of resistance than most breeding lines over several summers of testing (data not shown). Even though the

resistance was good in spring 1992 (Table 3) and summer 1990 (Table 4) it was a disappointment in summer 1992 (Table 2). Fla 7421 may have a useful level of resistance, but it is not as resistant as Hawaii 7997. Thus, it may be missing a resistance factor linked to plant habit or fruit size. Furthermore, the breakdown of Fla 7421 and some other resistant cultigens in some replicates in 1992 (Table 2) and the less than total resistance of our best sources (Table 1) underscores the limitations of resistance when environment favours the pathogen.

Our results support earlier work that Hawaii 7997, CRA 66, and PI 126408 are good resistance sources (Sonoda and Augustine 1978). GA 1565 also had good resistance (Tables 2–4). GA 1565 was derived from PI 263722 which did well in previous testing (Sonoda and Augustine 1978). GA 219, which was derived from PI 126408, had been rigorously screened for two generations with seed saved from 2% and 55% of plants which survived (Jaworski et al. 1987). Yet in our testing GA 219 was remarkably similar to PI 126408 (Tables 2–3). This illustrates a major breeding problem. The difference between healthy and diseased plants is often due to non-genetic causes. Breeders save seed from healthy plants but too often superior resistance is not selected. The presence of healthy escapes in susceptible lines exacerbates the problem, as do difficulties in obtaining reliable results from inoculation (Somodi et al., these proceedings). In Florida, several resistant sources have been used but none has proven superior in developing breeding lines with a greater resistance level than the others. One possibility would be to combine resistances to obtain an enhanced level of resistance. However, it is difficult to know which ones to combine. If genetic mechanisms are different, then different genes can be assumed. But it is not known if they would enhance each other. If genetic control is similar, one cannot rule out that mechanisms may be different, and that they might enhance each other. Selecting for combined resistance also would be difficult due to screening limitations already discussed. Perhaps molecular linkage work will be useful in this regard, but that work is fragmented at present.

If this disease is to be overcome genetically, it will likely take a more coordinated worldwide approach. First, worldwide testing of all available resistance sources is needed. From this, the most broadly adapted sources could be identified, as would sources which would complement due to race differentials. If adequate molecular linkage markers were then found for these lines, crosses between them could be made with selection for the markers. Selected lines could then be tested on a worldwide basis. Although such an approach would take time and would not be easy, it would be more likely to solve the problem which needs to be identified on a global basis. The first step in the scientific method is to define the problem, and the interaction between resistant hosts, pathogen races and environment has not been defined on a global basis. In the meantime, we have our hands full trying to develop a variety for Florida.

Characterisation of *Pseudomonas solanacearum* and Evaluation of Tomatoes in Nepal

T.B. Adhikari*, J.B. Manandhar† and G.L. Hartman†

Abstract

Twenty-five isolates of *Pseudomonas solanacearum* from eggplant, marigold, pepper, potato, tobacco and tomato plants grown in two distinct agroclimatic zones, one in lowland subtropics (100 to 500 m above sea level) and the other in the high hills (900 to 1800 m above sea level) were characterised in terms of biochemical and physiological tests, and to pathogenicity on eggplant, peanut, pepper, potato, sesame, tobacco and tomato. Based on the biovar classification scheme, 8 isolates from high hills were placed in biovar 2 and the rest from lowland subtropics in biovar 3. On the basis of pathogenicity tests, 8 strains were race 3 and 17 strains were race 1. The nature of their occurrences suggests that biological and environmental factors play an important part in determining the distribution of biotypes. Race 1 and biovar 3 are first reports from Nepal. Tomato line CL1131 and variety Rampur Local were resistant to *P. solanacearum*.

BACTERIAL wilt caused by *Pseudomonas solanacearum* E.F. Smith is one of the most important and widespread bacterial diseases of crop plants in Nepal. The disease was first reported in early 1960s in the Kathmandu valley 1300 m above sea level (Shrestha 1977). The pathogen also affects eggplant, pepper, tobacco and tomato in the lowland subtropics (altitude 100–500 m) where the temperatures are hot in the summer and cool in the winter. Economic losses due to bacterial wilt may be greater for tomato than other crops, although most surveys have been done on potato, with infested areas in Dolakha, Kaski, Kathmandu, Makwanpur, Palpa and Sindhupalchok districts being examined (Shrestha 1977). Recently, bacterial wilt has also been observed at Ghandruk, Sabet and Ulleri locations in the high hills altitude 1800 m) and the disease incidence in potato fields was estimated to be around 70% (Pradhanang and Dhital 1991, unpublished data).

*Department of Plant Pathology, Institute of Agriculture and Animal Sciences (IAAS), Rampur, Chitwan, Nepal.

†Asian Vegetable Research and Development Center (AVRDC), P.O. Box 42, Shanhua, Tainan 741, Taiwan, R.O.C.

P. solanacearum has been separated into races based on host range (Buddenhagen et al. 1962). Race 1 affects tobacco, tomato, many solanaceous plants, some weeds, and certain diploid bananas. Race 2 causes wilt of triploid banana, *Heliconia* spp. or both. Race 3 affects potatoes and tomatoes but is not highly virulent on other solanaceous crops. Hayward (1964) differentiated strains of the pathogen into four biovars depending upon their abilities to oxidise three disaccharides and three hexose alcohols. Biovar 1 oxidises none of the carbohydrates; biovar 2 oxidises only disaccharides; biovar 3 oxidises both disaccharides and hexose alcohols; and biovar 4 oxidises the hexose alcohols only.

P. solanacearum isolates from potato fields in Nepal were grouped into race 3 and biovar 2 (Shrestha 1977). Similar studies at Lumle Agricultural Center with strains isolated from potato revealed characteristics of race 3 and biovar 2 (Pradhanang and Dhital 1991, unpublished data). However, little is known about strains from the lowland subtropics of Nepal. In this region, tomatoes are grown throughout the year. This paper reports additional information on the identification and distribution of races and biovars of *P. solanacearum* from different crop plants in the central region of Nepal.

Materials and Methods

Isolation of the pathogen

Diseased specimens of eggplant (*Solanum melongena* L.), marigold (*Tagetes* sp.), pepper (*Capsicum annuum* L.), potato (*Solanum tuberosum* L.), tobacco (*Nicotiana tabacum* L.) and tomato (*Lycopersicon esculentum* Mill.) were collected from farmers' fields and kitchen gardens in lowlands and high hills during May 1989 to September 1991 as detailed in Figure 1 and Table 1. Stem sections of 15–20 mm long were cut with razor blades and placed in test tubes containing sterile water. After 5–10 minutes, when bacterial ooze was observed streaming out of the xylem, a loopful of the suspension was streaked on tetrazolium chloride (TZC) medium (Kelman 1954) and plates were incubated at 30°C for 48 hours. Three to five colonies of *P. solanacearum* were selected and maintained in sterile distilled water in screw-cap test tubes.

Biochemical tests

Unless otherwise specified, the isolates were identified using standard laboratory techniques (Hayward 1964; Sands et al. 1980; Winstead and Kelman 1952). Biochemical tests, Gram stain and microscopic examinations were used in addition to the observation on fluorescence on King's B medium (King et al. 1954). In addition, studies were made on the positive and negative reactions to acetone production, action on litmus milk, catalase and oxidase activities, effect of growth on 1, 3, and 5% sodium chloride, gelatin liquefaction, glucose utilisation, hydrogen sulfide production, hydrolysis of Tween 20, indole production, levan production, nitrate reduction, oxidation or fermentation tests, starch hydrolysis, and growth at various temperatures.

Susceptibility to antibiotics was tested with Bacto antibiotic sensitivity disks as recommended by the manufacturer (Difco Laboratories, Detroit, MI 48232).

Biovar determination

Basal media containing 1.0g $NH_4H_2PO_4$, 0.2 g; KCl, 0.2 g $MgSO_4.7H_2O$, 1.0 g peptone (Difco), 0.3 mL 1% bromothymol blue, and 18.0 g agar (Difco) per L were prepared to include one of three disaccharides (cellobiose, lactose and maltose) or three hexose alcohols (dulcitol, mannitol and sorbitol). The pH was adjusted to 7.1 with 40% NaOH (w/v) before addition of the agar. Five mL of 10% (w/v) solution of the previously autoclaved sterile carbohydrates were added to 45 mL of molten basal medium, which was then dispensed in sterile test tubes to a depth of about 4 cm as described by Hayward (1964). A loopful of bacterial cells of all 25 isolates was inoculated individually to each of six media. Cultures were incubated at 30°C for 28 days and monitored daily for colour change in the media.

Pathogenicity tests

Pathogenicity of all 25 isolates was tested on eggplant cv Norkee, peanut (*Arachis hypogaea* L. cv Janak), pepper cv California Wonder, potato cv Kufri Jyoti, sesame (*Sesamum indicum* L. cv Rampur Local), tobacco cv Belachapi and tomato cv Pusa Ruby. Seedlings of eggplant, pepper, tobacco, and tomato were transplanted in 30-cm diameter plastic buckets 3 weeks after sowing. Seeds of peanut and sesame, and potato tubers were planted directly in the plastic buckets. All plants were grown in the greenhouse at 28 ± 8°C.

Inoculum was adjusted to 10^8 cfu/mL and 10 mL of inoculum per plant was poured around the base of the plants. An alcohol-flamed knife was inserted 4–5 cm into the soil to cut the roots along one side, as described by Winstead and Kelman (1952). Ten plants of each of seven test hosts (mentioned above) were inoculated with each of the 25 isolates. Inoculated plants were placed on the greenhouse benches at 28 ±8°C. Severity of wilting was rated using the disease scale of He et al. (1983), in which 1 = no symptom, 2 = inoculated leaf wilted, 3 = two or three leaves wilted, 4 = four or more leaves wilted and 5 = plant dead.

Evaluation of tomato cultivars

Seeds of 15 tomato lines/cultivars obtained from the Asian Vegetable Research and Development Center (AVRDC), Shanhua, Tainan, Taiwan, the National Vegetable Development Division, Khumaltar, Lalitpur, Nepal, and the Horticulture Research Station, Bangalore, India were evaluated for resistance to *P. solanacearum* in the greenhouse. Two-week-old seedlings were transplanted in clay pots. The test plants were inoculated 3 weeks after transplanting. Isolate Tm9 was used as inoculum source for the experiment. Virulent colonies were selected on TZC medium and inoculum density was adjusted to 10^8 cfu/mL. Inoculated plants were incubated in the greenhouse at 28±8°C. The incubation period (IP = number of days required to develop visible symptoms) and latent period (LT_{10} = number of days required to produce 10% wilted plants) of each cultivar were regularly recorded after inoculation. The percentage of wilted plants was estimated each week for 5 weeks. From these readings, average percentage wilt (APW) was calculated, and a disease scale was developed to differentiate levels of resistance and susceptibility among tomato cultivars. The experiment, which was done twice, was set out in completely randomised block design with four replications. Means of two experiments were averaged to calculate IP, LT_{10} and APW.

Results

Biochemical tests

All strains were rod-shaped, motile and Gram-negative. On TZC agar medium, all virulent isolates produced fluidal colonies with pink or light-red centres in 48 hours. None of the isolates produced fluorescent pigment on King's B medium. All isolates grew rapidly at 30°C. Isolates Ep1, Pp2, Tb1 and Tm9 showed slight growth at 40°C. Isolates Pt6, Pt7 and Pt8 showed slight growth at 10°C. All isolates were negative for acetone production, gelatin liquefaction, indole production, 3% and 5% concentrations of NaCl and starch hydrolysis. All isolates were aerobic, and positive for alkaline reaction on litmus milk, hydrolysis of Tween 20, production of levan, nitrate and hydrogen sulfide, presence of catalase and oxidase activities, and growth in 1% NaCl.

All isolates tested were resistant to penicillin and tetracycline. However, isolates varied in their reaction to chloramphenicol, ciprofloxacin, gentamycin and norfloxacin (Table 2).

Biovar determination

Isolates differed in their ability to utilise three disaccharides and three hexose alcohols. Except for isolate Pt1-Pt8, which was negative to hexose alcohols, all isolates were positive to all carbohydrates except for isolate Pt1–Pt8 which was negative to hexose alcohols. According to Hayward's classification, eight of the 25 isolates were biovar 2 and the rest biovar 3 (Table 3).

Pathogenicity test

All isolates caused rapid wilting of tomato plants. Eggplant, pepper and tobacco plants showed marked differences in their reactions to specific isolates. Peanut plants were weakly susceptible to Ep1–Ep3, Pp2, Tb1, Tb2, Tm2–Tm6, and Tm9 isolates, while sesame plants were mildly susceptible to Tm1 and Tm2 isolates. Potato plants were susceptible to most isolates. Isolates were differentiated into two races on

Table 2. Susceptibility of 19 isolates of *Pseudomonas solanacearum* to antibiotics.

Antibiotic	Concentration (µg/mL)	Isolates			
		Ep1, Ep2, Pp1,Pt3, Pt5–Pt7, Tm1, Tm3, Tm8, Tm9	Pp2, Tb1, Tm2, Tm5, Tm6	Pt2, Pt4	Ep3
Chloramphenicol	30	R-WS[a]	R	S	S
Ciprofloxacin	5	R	S	S	R
Gentamycin	10	R-WS	R	S	R
Norfloxacin	10	R-WS	S	WS	R
Penicillin	10	R	R	R	R
Tetracycline	30	R	R	R	R

[a]R = resistant, zone of inhibition absent; S = susceptible, wide zone of inhibition (>12 mm); and WS = weakly susceptible, zone of inhibition indefinite or small (<11 mm).

Table 3. Biovar determination of 25 isolates of *Pseudomonas solanacearum* using six carbohydrates.

Carbohydrate	Isolates of *Pseudomonas solanacearum*

Sorbitol	+	–

[a]+ and – denote positive and negative responses.

the basis of host reaction. Isolates from host plants other than potato were members of race 1, whereas isolates from potato plants were race 3 (Table 4).

Evaluation of tomato cultivars

The IP, LT_{10}, APW and reaction of tomato lines/cultivars were significantly lower in CL1131 and Rampur Local compared with all other test lines (Table 5). Of the 15 cultivars tested, four cultivars (CLN475 series) were susceptible, six (AC282, CLN475BC1F2-274-0-15-0, CLN5915 series) were moderately susceptible, three (AC111, AC142 and BWR1) were moderately resistant and two (CL1131 and Rampur Local) were resistant.

Discussion

The isolates did not vary in their biochemical tests except for the tolerance to chloramphenicol, ciprofloxacin, gentamycin and norfloxacin. Tolerance to penicillin (10 µg) and tetracycline (30 µg) by all isolates is probably inherent to the strains, since farmers are not known to apply antibiotics to their crops.

Isolates varied in their physiological characteristics. The races and biovars identified in this study were similar to those identified in other countries (Buddenhagen et al. 1962; Hayward 1964; He et al. 1983; Seneviratne 1969). The isolates from lowland regions in Nepal tested in our study were biovar 3 and race 1. In the absence of any evidence of the introduction of biovar 3 and race 1 from outside Nepal to the virgin soils of the lowland subtropics, it is suggested that *P. solanacearum* is endemic to these soils and is a normal component of the soil microflora, a situation similiar to that reported from Sri Lanka (Seneviratne 1969). The planting of susceptible tomatoes such as cv Pusa Ruby and its monoculture practice all year round in lowland

subtropics has no doubt contributed to the build up of inoculum and the importance of bacterial wilt. Tomato lines CL1131 and Rampur Local, which were identified as resistant in greenhouse tests, need to be rigorously field tested along with further tomato lines/cultivars at different locations.

Isolates belonging to biovar 2 were all from potato plants isolated from the high hills, confirming earlier reports (Pradhanang and Dhital 1991, unpublished data; Shrestha 1977; Shrestha 1988). High hills of the Andes are the source for both wild potatoes and biovar 2 (race 3) of *P. solanacearum*. It appears that this strain has now been spread throughout the world by latently-infected seed potatoes (Hayward 1991).

Resistance of Tomato Rootstock Cultivars to *Pseudomonas solanacearum* Evaluated by Infection Rate under Different Testing Conditions

K. Nakaho and S. Takaya*

Abstract

Resistance of two tomato rootstocks (LS-89, BF-Okitsu 101) and one commercial cultivar (Ponderosa) to *Pseudomonas solanacearum* was evaluated by determining the infection ratio of the infection as well as by observing symptoms under conditions in which three factors, leaf stage at the time of inoculation (from four to eight leaf stage), inoculum concentration (from 10^5 to 10^8 cfu/mL) and growing temperature of plants after inoculation (30°C–25°C and 25°C–20°C, day–night) were combined. Disease incidence was higher on younger plants, at higher inoculum concentrations and at higher incubation temperatures. Resistance of the rootstocks was clearly demonstrated especially when they were incubated at low temperatures, although the response of two rootstocks was not identical. The ratio of infection differed only slightly among rootstocks and the commercial cultivar, as there were many healthy looking but latently infected plants of the rootstocks under mild conditions for disease development.

MANY solanaceous vegetables, such as tomato and eggplant, are grown in succession or after a short rotation period involving one or two other crops in the same field, because greenhouse facilities are used to produce most other vegetables in Japan.

Under these circumstances, bacterial wilt caused by *Pseudomonas solanacearum* is severe and the countermeasure commonly adopted is use of resistant rootstocks.

Many efforts have been made to obtain rootstocks with good resistance. In such studies, wilted and dead plants were used as a criterion for evaluation and little attention was paid to latently infected plants. However, such plants, if they exist, might wilt under different environmental conditions and although appearing healthy they may cause wilt on the grafted commercial cultivars.

In our study, resistance of commercial cultivars and rootstocks was evaluated by infection rate and compared to visual ratings of wilt. The objective was to clarify how three factors—leaf age at the time of inoculation, inoculum concentration and temperature of growth of plants after inoculation—interact to influence the disease incidence and the infection rate of two resistant rootstocks and a susceptible commercial cultivar.

*Chugoku National Agricultural Experiment Station, 6-12-1, Nishifukastu, Fukuyama, Hiroshima 721, Japan.

Materials and Methods

Two resistant rootstocks, LS-89 and BF-Okitsu 101, which are the most common tomato rootstocks in Japan, and LS-89, a selection from Hawaii 7998 and BF-Okitsu 101 (NC•1953-64N, received from North Carolina State University) were used along with Ponderosa, a susceptible cultivar. Plants were grown individually from seed in peat moss pellet (Jiffy-9, 50 mm single, Jiffy Products Ltd) in the greenhouse until seedlings reached from four- to eight-leaf stage. Plant age at the time of inoculation was expressed by number of leaves.

The bacterial isolate used was 8107 (biovar 4) obtained from a diseased tomato plant at Nara Prefecture in Japan. The culture was stored in 10%(w/v) skimmed milk at –20°C to reduce development of avirulent mutants.

Prior to inoculation, the bacterial suspension was streaked on to the selective agar medium of Hara and Ono (1983) and incubated at 30°C for 48 hours. Individual virulent colonies were removed and suspen-

sions in distilled water were adjusted to a concentration from 10^8 to 10^5cfu/mL by serial dilution in conjunction with a Bausch and Lomb Spectronic 20 colorimeter.

Inoculations were made by dipping trimmed roots in the bacterial suspension in plastic cases. Plants were kept in growth chambers set at 25–30°C (day) and 20–25°C (night) and illuminated by ca. 30000 lux light intensity with 12-hour photoperiod.

Final observations of wilted plants and disease ratings were made 14 days after inoculation following the system of Winstead and Kelman (1952). Symptomless plants were examined for latent infection as follows: a piece of stem 2 cm in length was cut from basal portion and dipped in a test-tube containing 3 mL distilled water. After incubating at 5°C for 12 hours, the test-tube was vortexed and 20 mL of the suspension was plated onto Hara and Ono's selective agar medium and cultured at 30°C for 48 hours. Virulent colonies were distinguished from other bacterial colonies on the agar medium by their appearances. Number of plants used in a treatment was from eight to ten. Experiments were repeated two or three times.

Results

For LS-89 under high temperatures almost all plants wilted or died when they were inoculated at the four-leaf stage (Fig. 1). Fewer plants wilted as the leaf stage advanced and the inoculum was diluted. The number of latently infected plants inoculated at the eight-leaf stage was nearly twice that of wilted plants. Under low-temperature conditions, there were only a few wilted plants, but latently infected plants were recognised regardless of leaf stage at time of inoculation, especially when the plants were inoculated at the four-leaf stage, as more than 50% of them were latently infected.

For BF-Okitsu 101 under high temperatures almost all plants wilted (Fig. 2). Under low temperatures, plants wilted when inoculated at the five- and seven-leaf stage. The number of wilted and latently infected plants decreased as inoculum was diluted. At the eight-leaf stage, plants did not wilt, and 10 to 40% were latently infected.

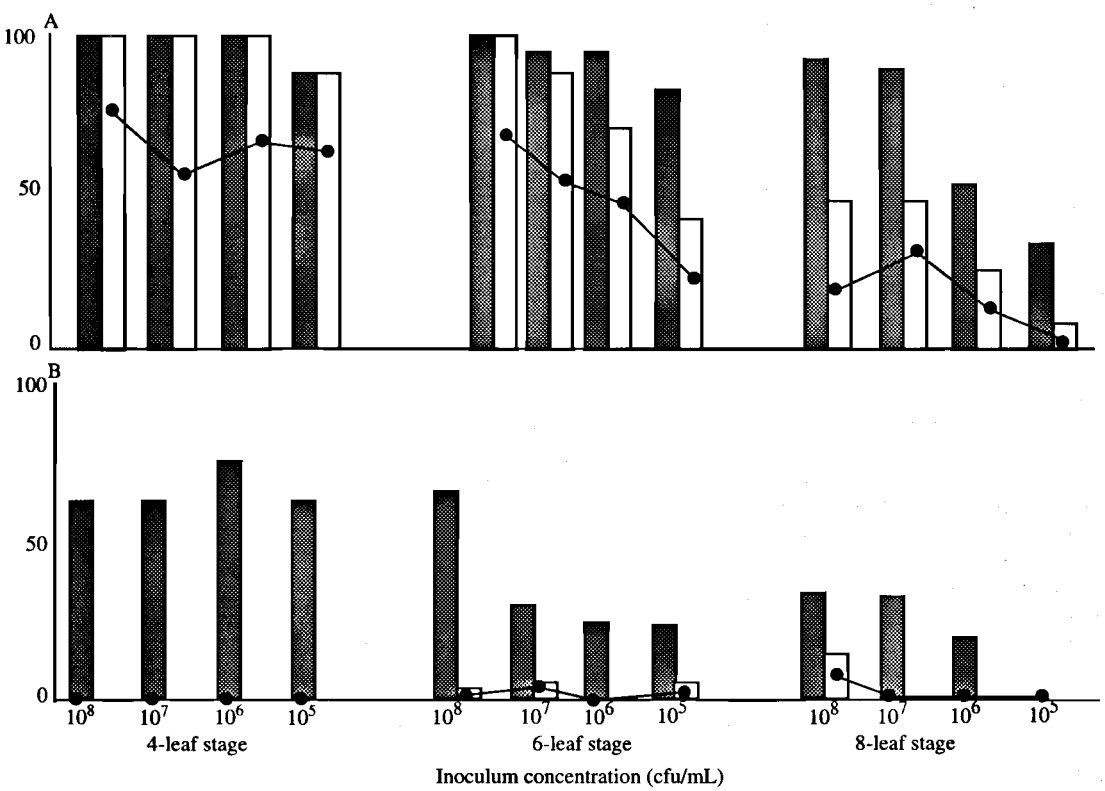

Fig. 1. Percentage of wilted and infected plants and disease index of LS-89 inoculated with *Pseudomonas solanacearum* at four concentrations, at three different leaf stages and grown at A) high temperature condition (30°C/25°C day/night), and B) low temperature condition (25°C/20°C). ■ Infected plants (%); □ Wilted plants (%); and ● disease index.

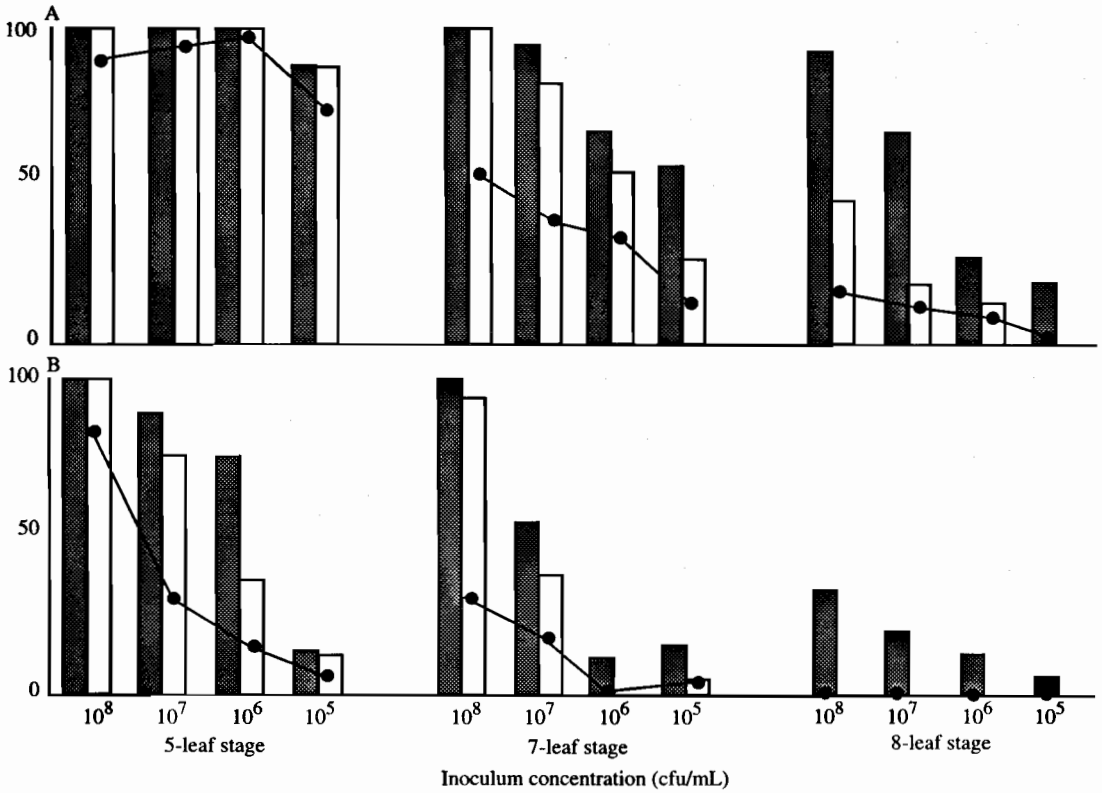

Fig. 2. Percentage of wilted and infected plants and disease index of BF-Okitsu 101 inoculated with *Pseudomonas solanacearum* at four concentrations at three different leaf stage and grown in A) high temperature (30°C–25°C day–night), and B) low temperature (25°C–20°C). ▩ Infected plants (%); □ Wilted plants (%); and ● disease index.

When comparing wilt percentage of LS-89 and BF-Okitsu 101, the effect of two different growth temperatures differed significantly, as more plants of LS-89 wilted than of BF-Okitsu 101.

For Ponderosa under high temperatures all plants wilted except at the lowest inoculum concentration regardless of leaf stage at the time of inoculation (Fig. 3). Under low temperatures, the final results were essentially the same as those at high temperatures, although disease indexes were slightly lowered.

Virulent colonies were detected on Hara and Ono's selective agar medium from plants of all three cultivars which did not have brown discolored vascular bundles.

Discussion

There are few reports in which the resistance of tomato cultivars tested for resistance to bacterial wilt was assessed on the basis of infection rate.

Hitherto, results obtained by evaluation of ratio of diseased plants and disease index in our experiments, were compared to those already reported (Krausz and Thurston 1975; Mew and Ho 1976, 1977; Winstead and Kelman 1952), and no great differences were apparent.

The disease incidence increased when plant age at time of inoculation was younger, and inoculum concentration and incubation temperature were higher. Resistance of rootstock cultivars was clearly demonstrated especially when they were maintained after inoculation at low temperature conditions, though the response of two rootstock cultivars differed.

However, when infection rate was used to evaluate the resistance, differences between rootstock and commercial cultivars were less apparent, although the trend in the data was the same as that obtained by the former method. There were many healthy looking, but latently-infected plants in rootstock cultivars under mild conditions for disease expression.

These observations lead us to suggest that resistance of the two rootstock cultivars is quantitative in nature and variable under different conditions.

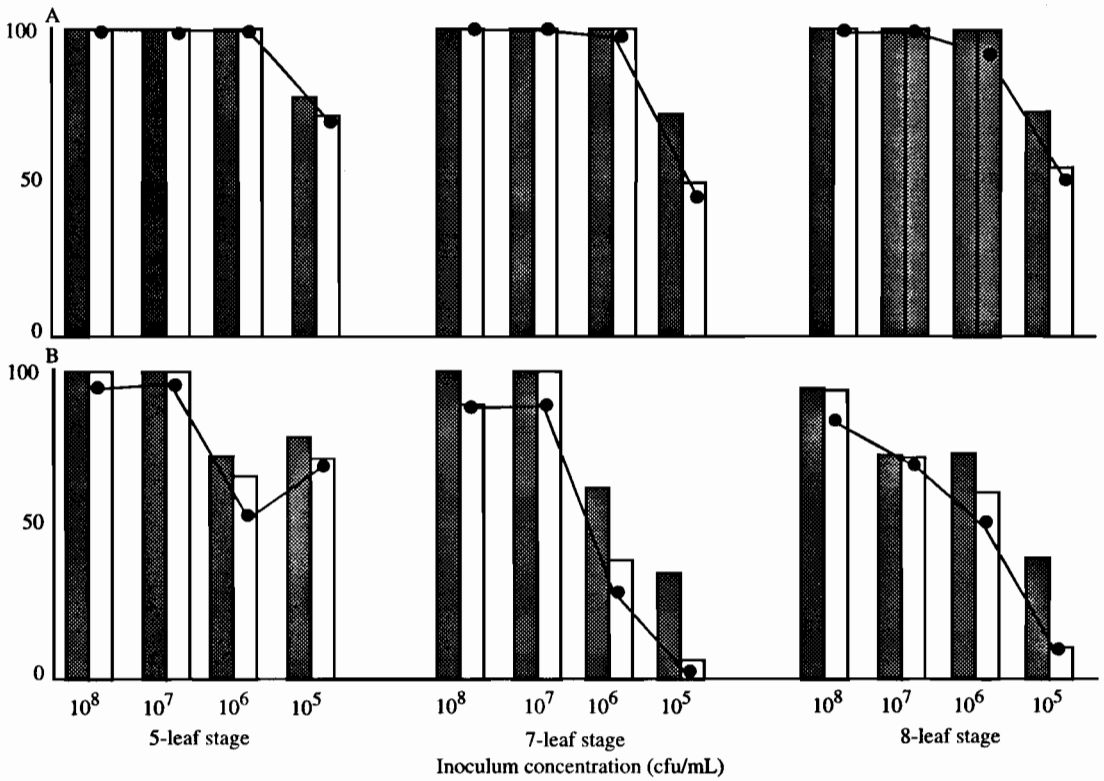

Fig. 3. Percentage of wilted and infected plants and disease index of Ponderosa inoculated with *Pseudomonas solanacearum* at four concentrations, at three different leaf stage and grown in A) high temperature (30°C–25°C day–night), and B) low temperature (25°C–20°C). ▩ Infected plants (%); □ Wilted plants (%); and ● disease index.

These results suggest that it would be useful to clarify the mechanism of the resistance in rootstock cultivars as well as continue to find new sources of resistance genes to enable development of better commercial cultivars of tomato.

Resistance to Bacterial Wilt in Tomato: Gene Dosage Effects

N. Anand*, A.T. Sadashiva*, S.K. Tikoo†, Ramkishun§, and K. Madhavi Reddy*

Abstract

Sixteen breeding lines and exotic introductions of tomato were identified as having resistance to *Pseudomonas solanacearum*. Two experiments were designed to elicit information on (i) behaviour of F_1s for disease resistance using lines differing in levels of resistance, (ii) genetic makeup of resistant lines, and (iii) possibilities of exploiting heterosis for yield with these lines. In the first experiment, several parents differing in survival rates were used in a diallel cross. F_1s showed dominance for resistance in two parents and recessive in one. F_1 from a cross of two moderately resistant parents had higher levels of resistance, indicating additive gene action. High level of resistance was reflected by high survival rates, reduced browning of vascular tissue and absence of ooze. In the second experiment, seven resistant (R) lines, including two from the previous set, were crossed with a susceptible (S) line and among each other. Twenty F_1s among R × R parents and nine F_1s of R × S and F_2s of R × R and R × S were studied. Although all the R parents had 100% survival, F_1s of R × S had variable survival percentages, indicating differences in levels of dominance among the resistant parents. Vascular browning, indicative of bacterial invasion, was used as a selection criterion for resistance. F_1s of R × R crosses with parents differing in genetic systems for resistance had higher levels of resistance than R × S crosses, suggesting complementation of resistance genes. Segregation ratios of R × R clearly indicated the nonallelic nature of resistance genes in four of the parents. Significant heterosis for yield in both experiments indicated greater genetic diversity for yield and its components. This was also evident among the parents. In the development of durable bacterial wilt resistant F_1 hybrids, it is essential that both parents carry resistance genes at different loci, so as to utilise the gene dosage effects for enhanced resistance in an appropriate genetic background.

BACTERIAL wilt caused by *Pseudomonas solanacearum* E.F. Smith is a devastating soilborne pathogen in the tropics. In India it causes serious economic losses in the states of Kerala, Karnataka, Orissa, Maharashtra, Bihar, West Bengal and Himachal Pradesh. In a bid to combat this disease, breeding efforts have been under way at our Institute for over two decades. Several resistant sources have been identified and two varieties, Arka Adha and Arka Alok, have been released for commercial cultivation.

F_1 hybrid tomatoes are rapidly gaining popularity among growers in India. It is therefore essential to develop bacterial wilt resistant F_1 hybrids that are durable over space and time. The nature of a resistance will determine its durability. Several types of gene action have been attributed to bacterial wilt resistance, including: multiple recessives (Tikoo et al. 1983); single dominant gene (Tikoo et al. 1983); partial dominance in the seedling stage and recessive genes in mature plants (Acosta et al. 1964); semi-dominant genes (Anais 1986); partial dominance (Digat and Derieux 1968); polygenic, additive (Ferrer 1984), monogenic partial dominance (Rajan and Peter 1986); additive gene action (Villareal and Lal 1978) and multiple recessive genes acting additively (Anon. 1975). Conflicting conclusions about the genetic control of resistance could be attributed to strong genotype × environment interactions involving polygenic

systems in both host and pathogen (Arnold and Brown 1968). Studies on development of resistant F_1 hybrids with different gene actions for resistance have not been reported.

The objectives of our study were to use parents with varying levels of resistance to bacterial wilt as well as to study the levels of resistance in F_1s when parents with different inheritance for resistance to this disease were employed so as to arrive at a strategy to develop durable resistant F_1 hybrids.

In the first experiment, several parents differing in survival rates were used in a diallel cross (Table 1). In the second experiment, seven resistant (R) lines, including two from the previous set, were crossed with a susceptible (S) line and among each other (Table 2).

To study the inheritance of resistance to bacterial wilt the following F_2 combinations were also studied among resistant crosses (R × R): BWR 5 × 1661, BWR 5 × 15 SB, BWR 5 × 1881, 1881 × 1661, 1661 × 1643, 1643 × Sonali, and BWR 1 × BWR 5; and the following F_2 crosses among R × susceptible (S) combinations: 1661 × 977, 1881 × 1817, 15 SB × 1816, and 1643 × 1817.

The experiments were carried out between 1986 and 1992. The prevailing maximum temperature during crop growth periods ranged from 29 to 36.6°C and the minimum temperature from 14.1 to 22.8°C. In parents and F_1s, 15 plants were replicated three times. For F_2s, 150 seedlings were planted out at a spacing of 90 × 30 cm in wilt-sick soil and fertilized with 120 kg N/ha and 60 kg K/ha. Four harvests were made and yield per plant computed by dividing each plot yield by the number of transplants. Carbofuran was applied at 3 g/m^2 to control nematodes. Virulent colonies of *P. solanacearum* were identified on peptone casein hydrolysate agar containing 0.005% 2,4,5-triphenyl tetrazolium chloride (Kelman 1954), multiplied on nutrient agar medium and incubated at 30±1°C. After 48 hours of growth on nutrient agar medium, the pathogen was suspended in water and inoculated to leaf axils using two drops per 20-day-old transplant.

The survivors were counted on the 100th day. The spread of the pathogen was assessed by recording at final harvest, the degree of browning of split stems at the root-shoot junction. Three plants per entry from each replicate were rated on the following scale: 0 = no browning; 1 = light brown colour, spread restricted to 2 cm from the point of inoculation; 3 = dark brown colour, widespread browning of vascular tissue. Bacterial ooze was observed by dipping a piece of the lower cut stem from just above the root zone in a tube of clear water. The scoring for ooze was as follows: 0 = no ooze; 1 = thin strand of ooze not continuous, flow stops after 3 minutes; 2 = continuous thin white, flow not restricted; 3 = heavy ooze, turning the water turbid within 2 minutes.

Results and Discussion

Survival percentages of the parents in the diallele set ranged from 0 to 100% (Table 3). The F_1s of IHR 719, BWR 4 and BWR 9 crossed to Pusa Ruby showed complete resistance, indicating control by dominant gene(s) in these parents. BWR 4 and BWR 9 had no vascular browning or ooze, indicating that these sources of resistance reduced multiplication of the pathogen in the plant system. Prior et al. (1990) used ELISA at various stem levels in four cultivars of tomato and reported that three of them had field tolerance because their vascular systems were invaded, while in the fourth variety the pathogen was not detected. Association between vascular browning and ELISA tests may help elicit information on presence and multiplication of bacteria.

The moderately resistant lines, IHR 821 and BWR 13, had scores of less than 3 for browning and less than 2.2 for ooze, while the susceptible line Pusa Ruby was rated 3 in both tests. Moderately resistant lines IHR 821 and BWR 13 when crossed with resistant parents, produced highly resistant F_1s. F_1s of IHR 821 and BWR 13 crossed with CRA 66 Sel A, [known to possess recessive polygenes for resistance (Tikoo et al. 1983)] had higher levels of resistance than IHR 821 or BWR 13. Moderate resistance in IHR 821 and BWR 13, controlled by many genes acting additively and in combination with those of CRA 66 Sel A, resulted in resistant F_1s. Additive gene action for resistance to bacterial wilt has also been reported by Ferrer (1974), Graham and Yap (1976), Villareal and Lal (1978), and at AVRDC (Anon. 1990; Hartman 1992). Further proof of additive gene action conferring resistance arises from the F_1 of IHR 821 × BWR 13 which had a higher survival percentage than either of the parents, and had significantly lower browning and ooze scores (Table 3).

In studies on resistance, none of the plants in the seven resistant parents wilted, while the susceptible lines had less than 10% survival (Table 4). F_1s of BWR 1, BWR 5, 1661, 15 SB and 1836, crossed with susceptible lines had 100% survival, indicative of dominant gene action, while F_1s of 1881 and Sonali had 80% and 50% survival, respectively, and had low ooze scores, indicating incomplete dominance for resistance to bacterial wilt. These results suggest differences in inheritance of resistance among the selected resistant lines and confirms the dominance in BWR 1 reported by Tikoo et al. (1983).

F_1s of crosses among bacterial wilt resistant lines having complete dominance had very high levels of resistance. F_1s of crosses between resistant parents (BRW1, BWR5, 15 SB and 1661) and a susceptible parent also had 100% survival (Table 4). However, the mean scores of browning were significantly less in R × R set of F_1s compared with the set of R × S F_1s indicating that multiplication of the pathogen was inhibited in the vascular system of the heterozygote from two resistant parents (Tables 4 and 5).

F_1s of crosses between resistant lines having dominant gene action (BWR 1, BWR 5, 15SB) and incomplete dominance (1881 and Sonali) exhibited high levels of resistance and low scores for browning. F_1 of Sonali with all other resistant lines including

1881, again had high levels of resistance confirming complementation of genes for resistance. Expression of resistance in the heterozygotes in our study had reduced multiplication, shown by low browning scores and lack of ooze. These parameters may be useful for selection of resistance in segregation populations.

Even the resistant lines BWR 4, 1661 and 1881 showed slight browning (Table 4). Linear advance of the pathogen in the vascular tissue may be related to cell multiplication rate, resulting in different levels of resistance. Resistance also could result from the ability of the host to produce toxin in areas where the pathogen is active, so as to check its spread. Lines having vascular browning should be avoided when more-resistant lines are available, as they may display reduced levels of resistance at higher temperatures. Resistance to bacterial wilt was reported to be temperature sensitive and strain specific (Krausz and Thurston 1975). Whether this is primarily a function of virulence factors expressed at high temperatures (Tung et al. 1990b), or the lack of expression of resistance genes, is not known. Terminologies related to resistance or susceptibility may become clearer when techniques such as DNA probes, monoclonal antibodies, and ELISA are available to test bacterial populations in the host plant.

Variances of general and specific combining ability obtained through diallel analysis (Table 6) indicated that both additive and nonadditive gene actions were important. The additive genetic variance and the dominance variance were important with dominance variance the more so. Importance of nonadditive gene action was indicated by resistance in F_1s of R × S crosses. Nonadditive gene action has also been implied for bacterial wilt resistance at AVRDC (Opeña et al. 1990). Resistant parents differing in level of resistance

and genetic systems can additively enhance levels of resistance (Opeña et al. 1990). Interactions among resistant genes can be complementary when two or more nonallelic resistance genes confer resistance (Russell 1978).

F_2s among BWR 1, BWR 5 and 15 SB (a derivation of BWR 1) had 100% survival (Table 7). These parents have similar genetic systems for resistance, although backcross data are required to confirm allelism. F_2s of crosses among 1661, 1881, 1643 and Sonali, and between each of these and BWR 1 and BWR 5 had 70-85% survival. This indicates that the former set of resistant lines differ from each other in the resistance factors they carry and also differ from BWR 1 and BWR 5. Only F_2s involving parents carrying resistance gene(s) at identical loci are expected to show 100% survival.

Exclusive cultivation of a single genotype can exert strong selection pressure on the pathogen. Velupillai and Stall (1984) indicated that a shift in the population of *P. solanacearum* towards more aggressive strains was possible. Nonallelic heterozygotes differing in resistance genes would help combat more strains of the pathogen. In the absence of markers, better procedures are needed to identify different resistance genes in segregating populations, to enable pooling of these genes. This could be a form of genetic diversification whereby the pathogen would have to cope with a variety of resistance genes.

Heterosis for yield is a function of genetic diversity among the parents. The parents involved in both the experiments were morphologically distinct. BWR 13 was the highest yielder among those tested in the diallel set. It was a moderately resistant line with levels equal to BWR 5, BWR 4 and BWR 9 (all resistant lines), and was significantly higher yielding than IHR 821, Pusa Ruby and CRA 66 Sel A. Eight of the F_1s in the first experiment showed heterotic yields over the best parent (Table 3). The F_1 of IHR 821 × BWR 5 had the highest yield (1.79 kg/plant) followed by the F_1 of BWR 5 × BWR 9 (1.73 kg/plant) and BWR 4 × BWR 9 (1.58 kg/plant). Heterotic yields in R × R crosses were as high as in R × S or R × MR crosses. Genetic diversity for yield and its components was obviously high among

Table 7. Survival of F_2s inoculated with *Pseudomonas solanacearum*.

Crosses	Survival %

the parents used. Widening the genetic base for both resistance and adaptation to the environment (Tung et al. 1991a,b) may be very important in breeding for bacterial wilt resistance.

In experiment 2, heterosis of a high order was manifested in F_1s (Table 5). The over all heterosis in F_1s was 26.8% over the mean yield of resistant parents. F_1 hybrids in this experiment were grouped as follows: A = when both parents were resistant and resistance was governed by dominant genes; B = when one of the parents had resistance governed by dominant genes and the other by incompletely dominant genes (above 80% and 50% survival); and C = when both the parents had resistance controlled by incompletely dominant genes. The mean yield of F_1s in Group A was 2.48 kg/plant. In Group B, F_1s among parents having incomplete dominance (80% survival) yielded 2.59 kg/plant, while F_1s between parents with incomplete dominance (50% survival) yielded 2.17 kg/plant. In Group C, the mean yield of F_1s was 2.46 kg/plant. Heterosis for yield in F_1s of R × R could be independent of the nature of resistance in the two parents. This could be tested by growing these in soil free from bacterial wilt.

Wide genetic diversity exists among the lines, for yield as well as for bacterial disease resistance. This provides an opportunity for widening the genetic base for resistance, transferring resistance genes into appropriate genetic background thereby enlarging the scope of exploiting F_1 hybrids for resistance and yield. F_1s for R × S parents were as high yielding as R × R crosses when grown under bacterial wilt infested soil and if artificially inoculated. Constructing genetically diverse resistant parents would consume time and effort, and it may be worth while exploiting R × S crosses pending the development of a wider array of resistant lines with a broader genetic base, different genetic systems for resistance, and high in general combining ability.

The development of potential parents with bacterial wilt resistance genes will require identification of resistance genes at different loci, as well as the full complement of minor genes, modifiers, and multiple genes or polygenes. Tracing isozymic linkages if available or RFLP mapping can help in this effort. Use of serological techniques, such as raising antisera against several different isolates, identification of the most virulent pathotype, and application of ELISA to detect pathogen population in different field-resistant lines, could form the basis for a more refined classification of resistance. Screening using these methods may be more reliable and rapid.

Single plant selections with complete absence of browning have been made in F_2 and F_3 generations in wilt-infested soil from R × R crosses, after inoculation with bacterial suspension. Screening under heavy pathogen load, aided by the use of polyclonal antisera, will help to develop stable resistant lines.

Inheritance of Resistance to Bacterial Wilt in Tomato

S. Monma and Y. Sakata*

Abstract

Bacterial wilt resistant tomato lines D-9 and Hawaii 7998 were crossed with susceptible TPL-5. Resistance of the cross between D-9 and TPL-5 was evaluated in 1989, and TPL-5 and Hawaii 7998 in 1990. Parents, F_1s, F_2s and backcross plants were transplanted into a field heavily infested with *Pseudomonas solanacearum* and inoculated with the pathogen by pouring a bacterial suspension into the soil. Bacterial wilt resistance was evaluated by recording the date of plant death and by a resistance index (RI) from 1 (susceptible) to 13 (highest resistance) for each plant. The RIs of the resistant parents, D-9 and Hawaii 7998, were 12.8 and 13.0, and those of the susceptible parent, TPL-5 were 1.0 and 1.1, respectively. Mean RIs of the F_1 generation of the two crosses were 4.5 and 6.2, which were lower than each mid-parent value of 6.9 and 7.1, respectively. This suggests that the bacterial wilt resistance was partially recessive as there was incomplete dominance towards susceptibility. No correlation existed between RI and fruit weight in the F_2 generations of the two crosses ($r = -0.074$, $r = -0.019$). This indicated that it was possible to select plants possessing both high resistance to bacterial wilt and large fruit.

BACTERIAL wilt caused by *Pseudomonas solanacearum* E.F. Smith is one of the major problems of tomato in southeastern Japan, from Kantoo area of the main island to Kyushu Island. The disease causes heavy losses in tomato production, as application of chemicals, soil fumigation and crop rotation are practically ineffective. The use of resistant varieties is the most effective means for control of bacterial wilt. There are no fresh market varieties possessing both high resistance and high fruit quality available, whereas several highly resistant rootstock varieties have been developed. Growers have been grafting fresh market varieties onto resistant rootstocks to avoid bacterial wilt infection in infested areas. Grafting, however, is a time and labor consuming practice and development of highly resistant fresh market varieties is in high demand.

Knowledge on the inheritance of resistance is important in breeding for resistance. A few experiments on the inheritance of resistance have been reported (Acosta et al. 1964; Ferrer 1974; Lum 1982) but the mode of the inheritance is still uncertain. This paper reports on the inheritance of the resistance in tomato to bacterial wilt.

*National Research Institute of Vegetables, Ornamental Plants and Tea, Department of Vegetable Breeding, Laboratory of Solanaceous Vegetable Breeding, Ano, Mie 514–23, Japan

Materials and Methods

Two resistant parents, D-9 introduced from Malaysia and Hawaii 7998 from Hawaii, and one susceptible parent, Tomato Parental line 5 (TPL-5), were used. D-9 (P_1) and TPL-5 (P_2), and TPL-5 (P_3) and Hawaii 7998 (P_4) were crossed to obtain F_1 seed. The F_1s were backcrossed to each parent and self-pollinated to obtain F_2 seed. Resistance of the cross between D-9 and TPL-5 was evaluated in 1989, and for the cross between TPL-5 and Hawaii 7998 in 1990.

Cross of D-9 and TPL-5. Seeds of P_1, P_2, F_1, BCP_1, BCP_2 and F_2 were sown on 7 March 1989 in a greenhouse. On 1 April, seedlings were transplanted to 9-cm plastic pots containing sterilised field soil. On 27 April, the seedlings were transplanted to a bacterial wilt infested field. A randomised complete block design was used with three blocks. Seven plants for the P_1, P_2 and F_1 generations, 14 plants for the BCP_1 and BCP_2 generations, and 48 plants for the F_2 generation were planted per block. Plants were staked and pruned.

P. solanacearum was isolated from a diseased tomato plant. A pure culture was multiplied at 30°C for 48 hours in Wakimoto medium (Wakimoto 1962). Bacterial concentration was adjusted to 2×10^8 viable cells/mL. On 17 July, 81-day-old transplants were inoculated by pouring 50 mL of bacterial suspension into the soil at the base of each plant.

For the evaluation of resistance, the date of plant death was recorded from 20 June to 26 August. Using this date, a resistance index (RI) from 1 to 13 was assigned to each plant (Fig. 1). The resistance categories described by the RI were as follows: 1–2 = susceptible; 3–5 = weak resistance; 6–8 = moderately resistant; 9–11 = high resistance; and 12–13 = highest resistance. On 7 and 12 July, fruits of each plant were harvested and weighed, and mean fruit weights were calculated for the evaluation of fruit size.

Cross of TPL-5 × Hawaii 7998. Seeds of P_1, P_2, F_1, BCP_3, BCP_4 and F_2 were sown on 5 March 1990 in a greenhouse. On 30 March, seedlings were transplanted to 9-cm plastic pots containing sterilised field soil. On 1 May, the seedlings were transplanted to a bacterial wilt infested field. Seven plants for the P_1, P_2 and F_1 generations, 14 plants for the BCP_1 and BCP_2 generations, and 49 plants for the F_2 generation were planted per block. On 28 June, plants were inoculated and the dates of death were recorded from 8 June to 10 August. On 5 July, fruits of each plant were harvested and weighed.

Results

Cross of D-9 × TPL-5 in 1989. A difference in frequency distributions of the RI between the resistant parent, D-9 (P_1) and the susceptible parent, TPL-5 (P_2) was evident and the RI frequency distribution of the F_1 was skewed towards the susceptible parent (Fig. 2). Almost all categories of resistant plants were observed in the BCP_1. On the other hand, there were no resistant plants in the BCP_2. The F_2 segregated in a discontinuous pattern and was skewed towards the susceptible parent. The plants with highest resistance comprised 6% of the F_2s.

The mean RIs of D-9 and TPL-5 were 12.8 and 1.0, respectively, and the mean RI of F_1 was 4.5, which was significantly lower than the mid-parent value of 6.9 (Table 1). The mean RIs of BCP_1 and BCP_2 were close to those of the mid-parent and susceptible parent, respectively. The mean RI of the F_2 was close to that of the F_1.

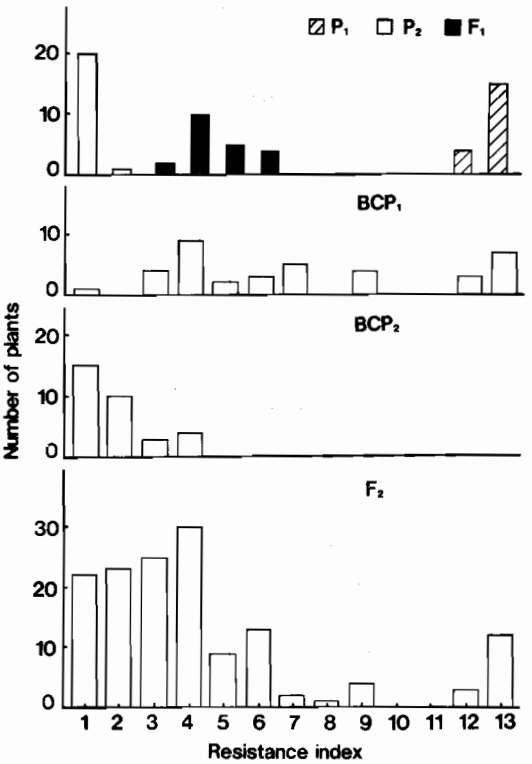

Fig. 2. Frequency distributions for bacterial wilt resistance index of resistant parent (P_1:D-9), susceptible parent (P_2:TPL-5), F_1, BCP_1, BCP_2 and F_2 generations. Higher numbers indicate higher resistance.

Fruits of four plants could not be harvested because of bacterial wilt. These four plants were excluded from the correlation analysis between resistance and fruit weight. No correlation was observed between RI and mean fruit weight among the F_2s (r = -0.074, Fig. 3).

Cross of TPL-5 × Hawaii 7998. A difference in frequency distributions of the RI between the susceptible parent, TPL-5 (P_3), and the resistant parent,

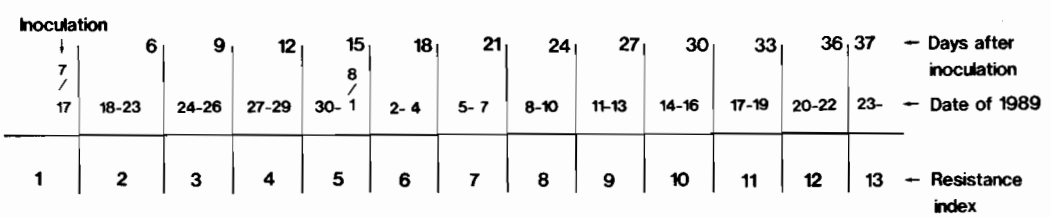

Fig. 1. Assignment of resistance index by the date of plant death in 1989.

Table 1. Bacterial wilt resistance index and fruit weight of parents, F_1, BCP_1, BCP_2, and F_2 generations in 'D-9' × 'TPL-5'

Parent and generation	Resistance index	Mean fruit weight (g)	Number of plants
P_1: D-9	12.8	69.6	19
P_2: TPL-5	1.0	145.0	21
F_1	4.5	145.0	21
BCP_1	7.3	101.6	38
BCP_2	1.9	127.0	32
F_2	4.4	118.7	144
Mid-parent value	6.9	107.3	–
LSD 5%	1.0	22.1	–
LSD 1%	1.4	31.5	–

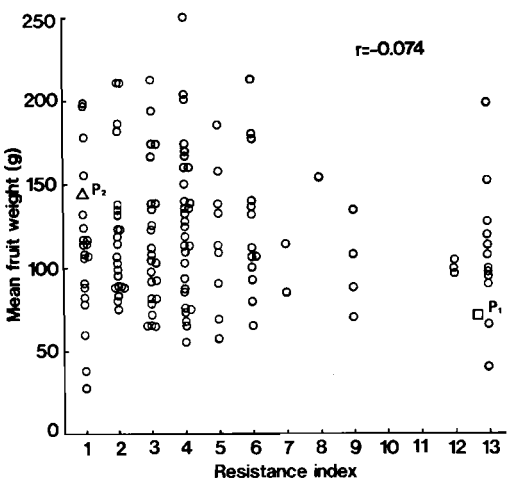

Fig. 3. Relationship between resistance index and mean fruit weight in F_2 generation of 'D-9' × 'TPL-5'. Higher numbers indicate higher resistance.

Hawaii 7998 (P_4) was evident (Fig. 4). The frequency distribution of the RI for the F_1 was between, but slightly less than, parental means. The range for this F_1 was wider than that of the F_1 from D-9 × TPL-5. All categories of resistant plants were observed in BCP_3. Almost all categories of resistant plants were also observed in BCP_4, in which plants with a RI of 13 showed the highest frequency. The F_2s segregated in a continuous pattern and the distribution skewed slightly towards the susceptible parent. The plants with highest resistance were observed to comprise 6% of the F_2s.

The mean RIs of TPL-5 and Hawaii 7998 were 1.1 and 13.0, respectively, and the mean RI of their F_1 was 6.2, which was slightly lower than the mid-parent value of 7.1 (Table 2). The mean RIs of BCP_3 and the F_2 were the same as that of the F_1. The mean RI of BCP_4 was higher than the midparent value.

Fruit of one F_2 plant could not be harvested because the plant died of bacterial wilt before fruit maturity. This plant was excluded from the correlation analysis between resistance and fruit weight. No correlation was observed between RI and mean fruit weight among the F_2s (r = -0.019, Fig. 5).

Discussion

Differences in methodologies for evaluating host resistance may affect the final interpretation of the inheritance of bacterial wilt resistance. The evaluation of resistance should be quantitative because resistance to bacterial wilt was reported to be controlled by several genes (Ferrer 1974; Lum 1982). Seedling inoculation methods such as clipping or root dipping have been applied for selection of

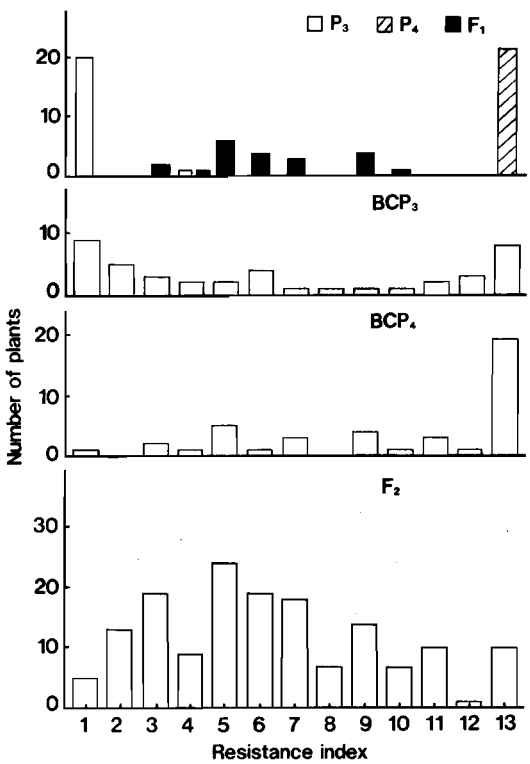

Fig. 4. Frequency distributions for bacterial wilt resistance index of susceptible parent (P_3:TPL-5), resistant parent (P_4:Hawaii 7998), F_1, BCP_3, BCP_4 and F_2 generations. Higher numbers indicate higher resistance.

F_1	6.2	61.3	21
BCP_3	6.3	65.6	42
BCP_4	9.8	58.2	41
F_2	6.3	66.0	156
Mid-parent value	7.1	90.5	–
LSD 5%	2.1	18.7	–
LSD1%	2.9	26.6	–

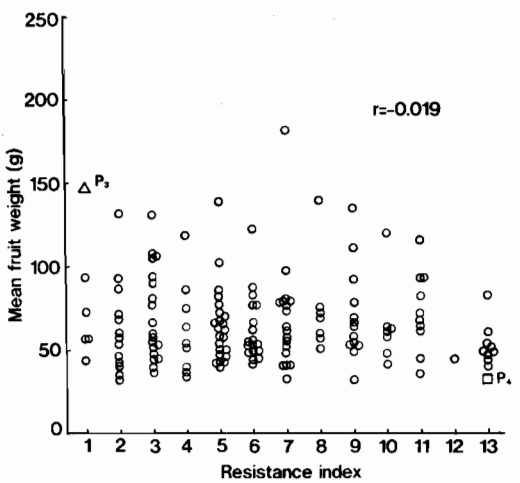

Fig. 5. Relationship between resistance index and mean fruit weight in F_2 generation of TPL-5 × Hawaii 7998. Higher numbers indicate higher resistance.

resistant seedlings, but the reaction of the inoculated seedling is usually death or survival. These results from artificial inoculation are qualitative. Although the varieties that survived the natural infection were either resistant, moderately resistant, or susceptible when inoculated (Mew and Ho 1976), it was pointed out that segregating populations were best screened under field conditions at the flowering stage (Mew and Ho 1976). The method used in this study was one that combined natural infection from infested fields with artificial inoculation to ensure disease. The resistance of each plant was shown by the resistance index (RI) according to the date of plant death. Differences in resistance classes among each parental line and generation were clear, indicating that the method could be used for the selection of resistant plants and for the evaluation of plant resistance in segregating populations.

It is important to understand whether or not bacterial wilt resistance in tomato is a dominant character because in Japan almost all fresh market varieties are hybrids. Acosta et al. (1964) demonstrated that resistance was partially dominant until 7 weeks after transplanting, but recessive in more mature plants. The RI of the F_1 in the cross of D-9 × TPL-5 was lower than the mid-parent value and the RI of the F_1 from the cross of TPL-5 × Hawaii 7998 was close to the mid-parent value. This suggested that the bacterial wilt resistance was partially recessive depending on the degree of resistance of the resistant parent. These result were similar to those reported by Acosta et al. (1964), where resistance was evaluated in mature plants.

It has been reported that several genes control bacterial wilt resistance (Ferrer 1974; Lum 1982) and that small fruit size was associated with resistance (Bosch et al. 1982; Ferrer 1974;) leading to the problem of developing a resistant variety with good commercial quality. The frequency distributions of the RIs of BCP_3 and the F_2 from TPL-5 × Hawaii 7998 showed a continuous pattern. This indicated that the resistance was quantitative, although the number of genes controlling resistance may be small because the frequency distributions of the RIs of BCP_1 and F_2 from D-9 × TPL-5 segregated in discontinuous patterns.

No correlations were observed between RI and fruit weight in the F_2 of the crosses. This indicated that selection of resistant materials for large fruit size was not a problem in resistance breeding, and that it was possible to select plants with both high resistance and large fruit weight in the segregating populations. This result contrasts with the results of Ferrer (1974) and Bosch et al. (1982).

Differences in frequency distributions of the crosses were evident, and the resistance of Hawaii 7998 was higher than the resistance of D-9. To explain the difference in resistance of the parents, it was assumed that the number of genes controlling resistance in Hawaii 7998 was greater than in D-9.

Virulence Studies of *Pseudomonas solanacearum* and Inheritance of Resistance in *Lycopersicon esculentum*

A.M. Mahir, K.S. Diong and A. Ismail*

Abstract

Eleven isolates of *Pseudomonas solanacearum* from different *Lycopersicon esculentum* plants grown in experimental plots at the Universiti Kebangsaan Malaysia and one ginger (*Zingiber officinale*) isolate from Universiti Pertanian Malaysia were tested for virulence using a stem-puncture inoculation method. The UPM ginger isolate was most virulent and was used to determine resistance and its inheritance in seven *L. esculentum* varieties. Local varieties (FP-5, Intan and MT-1) had relatively higher levels of resistance. Most of the imported varieties with improved agronomic characters were susceptible. Data from the F_1 hybrids and parents indicated that numerous modes of inheritance of resistance to *P. solanacearum*, including dominance, recessiveness, and additive gene action, were present. However, most resistances were conferred by a single dominant gene.

PSEUDOMONAS solanacearum E.F. Smith is one of the major diseases of *Lycopersicon esculentum* (tomato) in Malaysia, especially in the lowland areas. Use of resistant varieties from various breeding programs (Graham et al. 1977; Tan, unpublished data) and the Asian Vegetable Research and Development Centre (AVRDC) (Apandi and Mahir 1987; Tee et al. 1979) has not been effective in solving the problem.

Lack of understanding of the host, pathogen and environment might be one of the reasons for the limited success in controlling the disease. Understanding the host and pathogen is a prerequisite for devising proper methods of control. Disease resistances in most hosts interact with the pathogen and environment (Nelson 1977).

Breeding programs have been hampered partly because of differences in virulence and behaviour of isolates of the pathogen from different hosts (Abdullah 1986). Unfortunately, attempts to classify isolates have not always involved genetic interaction with the host plants, and few inheritance studies have used a wide range of isolates. Modes of inheritance of resistance have been shown to be: recessive and polygenic (Singh 1961; Anon. 1975); partial dominant at seedling stage and recessive at adult stage (Acosta et al. 1964); additive (Graham and Yap 1976); oligogenic (vertical resistance); polygenic (horizontal resistance); intermediate (Mew and Ho 1976); and complementary dominant (Screelathakumary and Peter 1984).

This preliminary study was conducted to investigate the relative virulence of isolates from different hosts, and the differences in virulence to various *L. esculentum* varieties; and to evaluate the modes of inheritance of resistance in *L. esculentum* germplasm.

*Department of Genetics, Faculty of Life Science, Universiti Kebangsaan Malaysia, 43600 Bangi, Selangor, Malaysia.

Materials and Methods

Variability of isolates

Eleven isolates of *P. solanacearum* were obtained from several diseased *L. esculentum* varieties from experimental plots of Universiti Kebangsaan Malaysia (UKM, National University of Malaysia). One *Zingiber officinale* isolate was from Universiti Pertanian Malaysia (UPM, University of Agriculture). Thirty 2-week-old seedlings of variety Sida KU [previously reported as susceptible (Rasheeda 1992, unpublished data)], were used to inoculate plants with each isolate in three replications. Three punctures were made in the stem at the axil of the third leaf with a sterile pin, and a sterile micropipette containing 20 μL of inoculum (630 nm =1.5 OD.) was immediately placed in the wounds.

The seedlings were rated 2 weeks after inoculation using the following scale: 0 = no symptom, 1 = one leaf partially wilted, 2 = two to three leaves wilted, 3 = all leaves except two to three terminal leaves wilted, 4 = all leaves wilted, and 5 = dead plant. A disease index (DI) for each isolate was computed using the following formula: $DI = n_0^{(0)} + n_1^{(1)} + n_2^{(2)} + n_3^{(3)} + n_4^{(4)} + n_5^{(5)} \times 100n \times 5$, where n = total number of plants, n_0 = number of plants with disease score of 0, n_1 = number of plants with disease score of 1, n_2 = number of plants with disease score of 2, n_3 = number of plants with disease score of 3, n_4 = number of plants with disease score of 4, and n_5 = number of plants with disease score of 5 (Winstead and Kelman 1952).

Differentation of virulence

The *Z. officinale* isolate (UPM) was the most virulent among isolates in a previous experiment and was used to inoculate 30 plants in three replications of seven *L. esculentum* varieties from three different geographical areas (The Netherlands, Thailand and Malaysia). Inoculation procedures and computation of disease index for each variety were as previously described. In addition, 30 plants of each variety were planted in three different experimental areas into infested field soil. The disease index of each variety was computed as previously.

Inheritance of resistance

The same seven varieties already mentioned, and their F_1 populations, were used to determine the inheritance pattern. Inoculation procedures and computation of disease index were as previously described.

Results and Discussion

Variability of isolates

The relative virulences of the 12 isolates of *P. solanacearum* on susceptible Sida KU are shown in Table 1. Disease index of the *Z. officinale* isolate was significantly higher than other isolates from *L. esculentum;* it killed most of the inoculated plants. All the *L. esculentum* isolates had lower than 20% disease index values. Among the *L. esculentum* isolates, the degree of virulence of isolates 1, 3, 10, 11 and 4 did not differ significantly. Isolates 10, 11, 4, 8, 5, 7, 2 and 9 did not differ significantly while isolate 6 was the least virulent. Isolates from different plant species differed in their virulence; while those from the same species but different geographical areas had similar disease index values.

With regard to the host, variety Sida KU was highly susceptible to the isolate from *Z. officinale*, but not to *L. esculentum* isolates. If a disease index of 50% is considered the cut-off point, then this variety was resistant to all isolates from *L. esculentum*. Sida KU could be considered to possess a gene for resistance that corresponds to a gene conditioning non-virulence in *L. esculentum* isolates and another gene for susceptibility that corresponds to a gene for virulence in an isolate from *Z. officinale*.

Differentation of virulence

Variety FP-5 had the lowest disease index (49.7%) when inoculated with the highly virulent isolate from *Z. officinale* (Table 2). The other six varieties had over 50% disease index values. Most of the imported varieties were susceptible. Both varieties from Thailand had significantly high disease index values. Local varieties fared well against the isolate.

The isolate from *Z. officinale* at UPM had specific differences in its virulence to various *L. esculentum* varieties, indicating that Sida THIP#2 may have a gene for susceptibility similar to that of Sida KU. Amateur had another specific gene for moderate susceptibility corresponding to a gene for moderate virulence in the pathogen. Both varieties Abunda and MT-1 had a

Table 1. Disease index values of Sida KU inoculated with various *Pseudomonas solanacearum* isolates.

Isolate		Source		Disease index (%)

Varieties	Origin	UPM's isolate(%)	Infested field (%)
Sida THIP#2	Thailand	91.53a[a]	48.00c
Sida KU	Thailand	90.54a	71.33b
Amateur	The Netherlands	74.42b	90.33a
Abunda	The Netherlands	63.00c	70.00b
MT-1	Malaysia	60.21c	40.33c
Intan	Malaysia	55.14d	24.67d
FP-5	Malaysia	49.74d	37.33cd

[a]Values with same letter denote non-significant difference ($P < 0.05$).

similar gene for low susceptibility, and both varieties Intan and FP-5 had similar genes for resistance.

Disease index values of all varieties differed under field conditions to those inoculated with the isolate from *Z. officinale*. All local varieties were stable in local habitat (Mak et al. 1979; Ho 1988), and had disease index values of less than 50%. Surprisingly, Sida THIP#2 also may have a low disease index which indicated that it had polygenic and horizontal resistance to various local *P. solanacearum* isolates. Amateur had the highest disease index (90.3%) and appears susceptible to all local isolates. Sida KU showed similar susceptibility to Abunda.

Inheritance of resistance

Numerous modes of inheritance of *P. solanacearum* resistance were observed in this experiment (Table 3).

Table 3. Disease index values of local, imported *Lycopersicon esculentum* parents and their hybrids inoculated with a ginger isolate.

	Intan	Sida THIP#2	MT-1	Sida KU	Sida THIP#2
Intan	55.1	64.1[a]			
Sida THIP#2		91.5	69.8[a]		
MT-1			60.2	69.1[a]	
Sida KU				90.5	81.7[b]
Sida THIP#2					91.5

	FP-5	Amateur	Abunda	MT-1
FP-5	49.7	58.8[a]		
Amateur		74.4	70.9[c]	
Abunda			63.0	53.7[d]
MT-1				60.2

[a]Dominant resistance.
[b]Pure susceptible.
[c]Recessive resistance/additive.
[d]Additive/heterosis.

Resistance was controlled mostly by a single dominant gene. This inheritance differed from those recorded in earlier reports (Acosta et al. 1964; Screelathakumary and Peter 1984). Disease index values of hybrids Intan × Sida THIP#2, Sida THIP#2 × MT-1, MT-1 × Sida KU, and FP-5 × Amateur were less than those of their respective midparents. The F_1 data suggest that resistance was largely dominant in different local *L. esculentum* varieties. Abunda, an imported variety, showed little resistance. This was recessive and additive when crossed to Amateur, and additive and heterotic when crossed with local variety MT-1. The disease index of the F_1 (Abunda × MT-1), suggests that heterosis for resistance may be expressed, with genes for resistance coming together from both parents. As expected, hybrids of both susceptible varieties from Thailand had a high disease index indicating similar genes for susceptibility.

Developing Bacterial Wilt Resistant F_1 Hybrids for Processing in Tomato (*Lycopersicon esculentum*)

H.V. Sathyanarayana and N. Anand*

Abstract

Tomato cultivation is severely affected by bacterial wilt caused by the soilborne pathogen *Pseudomonas solanacearum*. Attempts were made to exploit the dominant source of resistance combined with good processing qualities and yield. Line × tester analysis was performed using two lines with combined resistance to both bacterial wilt and nematodes, and three lines with resistance to bacterial wilt alone, as female parents in crosses with six testers having good horticultural qualities but susceptibility to bacterial wilt. All 30 F_1 hybrids exhibited a high degree of resistance (93–100% survival) to bacterial wilt. Seven of these hybrids were suitable for processing based on fruit size, firmness and colour. These hybrids had the following characteristics: high total soluble solids (4.7–5.8°B), lycopene (8.4–13.0 mg/100 g), acidity (0.31–0.46), pH (3.75–4.15) and a thick pericarp. The best F_1 was BWR15 × IHR 1614 which had a high lycopene (13.0 mg/100 g) content and an estimated yield of 76 t/ha. Eleven hybrids were classified as dual purpose types, both for processing and fresh market. Highest yielding F_1 among them was BWR5 × IHR 1032-1, which had a yield of 62 t/ha and an average fruit weight of 70 g.

TOMATO cultivation in the tropics is hampered by bacterial wilt, an important soilborne disease caused by *Pseudomonas solanacearum* E.F. Smith. The disease is widespread in India over the states of Karnataka, Kerala, Maharastra, Orissa and West Bengal, causing yield losses up to 90.6 percent (Ramkishun 1987).

In the absence of effective chemical control measures, growing resistant varieties appears to be at least a partial solution. Several sources of resistance to bacterial wilt have been reported in India like LE79 (Ramachandran et al. 1980), CRA66-Sel A (Rao et al. 1975), and IHR 663-12-3 (Tikoo et al. 1983). The following are the varieties released for commercial cultivation in India: Arka Abha and Arka Alok from the Indian Institute of Horticultural Research, Bangalore; Sonali from Akola, Maharashtra; and Shakti from Kerala Agricultural University, Kerala. The feasibility of exploiting the dominant source of genetic resistance to produce F_1 hybrids was explored by Tikoo et al. (1989).

The tomato processing industry is making rapid strides in India. With the increasing popularity of F_1 hybrids and the absence of wilt resistant hybrids in India, an attempt has been made to develop processing and/or fresh market hybrids resistant to bacterial wilt.

*Division of Vegetable Crops, Indian Institute of Horticultural Research, Hessaraghatta Lake, PO Bangalore 560 089, India.

Materials and Methods

A line × tester analysis was carried out using five lines and six testers. Two lines (SI-6 and SI-11) were resistant to both nematodes and bacterial wilt, while three others (BWR5, BWR14-1 and BWR15 SB) were resistant to bacterial wilt alone. The lines were used as female parents. Six testers with good horticultural qualities but susceptible to bacterial wilt were used as male parents (Tables 1 and 2).

The parents and hybrids having combined resistance to both nematodes and bacterial wilt were raised in seed pans with infested soil containing 100–120 larvae per 100 g of soil. The three wilt-resistant parents and their crosses were raised in nursery beds. Thirty-day-old healthy seedlings of 11 parents and 30 hybrids were transplanted in infested soil (10^8 cfu/g soil) in 3.5 m rows with a spacing of 90 cm between rows and 30 cm between plants in a randomised block design with three replications accommodating 11 plants per entry per replication. Twenty-five days after transplanting, a bacterial suspension of 0.5 OD (10^7 cfu/g soil) was inoculated into the third and fourth leaf

axils by piercing them with a needle to ensure the presence of sufficient inoculum.

The same set of parents and hybrids was also evaluated in noninfested soil to assess the genetic yield potential of hybrids. The fertilizer dose followed for both the trials was 60 kg N, 75 kg P_2O_5 and 60 kg K_2O per ha as basal dose and the same dose after 30 days, followed by 60 kg N 60 days after transplanting.

The percentage survival of each parent and crosses was recorded at 60, 90 and 120 days after transplanting. Quality parameters such as total soluble solids (TSS) were recorded using a refractometer. Lycopene content was estimated using the method developed by Adsule and Ambadan (1979) and pH recorded using a meter. Acidity was estimated following the methods of AOAC (1975). Statistical analyses were carried out using the methods of line × tester analysis (Kempthrone 1957).

Results and Discussion

Plants from the resistant parental lines had 100% survival. Up to 90% mortality was recorded in test material. All the F_1s were highly resistant to bacterial wilt (93.2–100% survival). The F_1s with S1-6 and S1-11 as one of the parents showed a high degree of resistance to nematodes. The delayed and low incidence of wilt (7%) coincided with high temperatures. The influence of temperature on the expression of resistant gene(s) has been reported (Monma and Sakata 1990; Sonada 1978).

The hybrids involved in this study were semideterminate, and the parents included were determinate and semideterminate types. The susceptible parents were selected based on processing qualities such as good pericarp thickness, high lycopene, low pH and acidity. Among 30 F_1s evaluated, seven hybrids were identified as suitable for processing having high TSS (above 5°B), high lycopene (above 8 mg/100 g), good pericarp thickness (above 0.75 cm) with low acidity (below 0.45) and pH (less than 4.5) (Table 3).

In India varieties that could suit the processing industry as well as fresh market would serve a dual purpose. Eleven F_1s were suitable for processing as well as the fresh market, based on the quality parameters and larger fruit size (above 60 g) (Table 4).

Pericarp thickness, which imparts firmness to fruits, helps to maintain longer shelf life. Pericarp thickness among parents ranged from 0.49–0.83 cm with the best parent, IHR 1614 having 0.83 cm. In hybrids the range was 0.46–0.83 cm. Since heterosis was not manifested for this characteristic, appropriate choice of parents is essential. Only eight F_1s exceeded 0.75 cm pericarp thickness.

Total soluble solids is a very important parameter for processing. High TSS above 5°B is preferable. Variability for TSS among parents ranged from 3.4 to 4.9°B. The range in F_1 hybrids was 4.0–5.5°B. Restriction in TSS can also be imposed by determinate or semideterminate plant growth. It may be difficult to build up high solids in determinate types. Ten hybrids recorded TSS above 5°B. The hybrids BWR 15 × 1032-1 recorded the highest TSS of 5.53°B with an average fruit weight of 69.2 g and an estimated yield of 62 t/ha.

High lycopene content is essential for both fresh market and processing fruit. Lycopene content among parents ranged from 3.0–11.1 mg/100 g. It was highest

[a]Total soluble solids.

in the parent IHR 1614 (11.1 mg/100 g). In hybrids it ranged from 8.42 in BWR-5 × 674 to 13.03 mg/100 g in hybrids of BWR 15 × 1614. Four hybrids recorded lycopene contents above 10 mg/100 g (Table 3). The parent IHR 1614 increased lycopene content among three of these hybrids—S1-11 × 1614 (10.6), BWR 14-1 × 1614 (12.03) and BWR 15 × 1614 (13.03 mg/100 g)—and was a good combiner for this trait (Fig. 1). The hybrid BWR 15 × 1614 exhibited 17.8% heterosis for lycopene over its best parent. Heterobeltosis was observed in hybrid BWR 14-1 × 1032-1 (86%). Narcisco and Rosario (1988) have also reported heterosis and heterobeltosis only for lycopene content among the processing quality parameters estimated.

Locule number is an important character that directly influences fruit firmness and seed content. Most of the previous studies have shown that hybrids are intermediate between their parents for locule number (Nandapuri and Tyagi 1976). This was confirmed in this study, with the parents having a range of 2.2 to 5.9 while in hybrids it ranged from 2.9 to 3.7 locules. Processing types generally have two to three locules. The other characters such as acidity and pH were within the limits required for processing.

Estimated yields of seven hybrids grown in nonin-fested soil and identified as suitable for processing ranged from 41.25 to 76.37 t/ha. The best among them was BWR15 × 1614 with a yield potential of

76.37 t/ha. It also was resistant to bacterial wilt and had an average fruit weight of 64.1 g. In addition, this hybrid had the highest heterosis (92.8% over mid parent), 85.9% heterobeltosis and 63.1% over the best parent, IHR 674. The other two promising F_1s BWR 15 × 1032-1 and BWR-5 × 674 recorded estimated yields of 62 t/ha (Table 3).

Eleven hybrids were considered to be useful both for processing and fresh market (dual purpose). Seven of these hybrids recorded higher average fruit weights (above 60 g). The best F_1 among them was BWR-5 × 1032-1 with an estimated yield of 63.87 t/ha and an average fruit weight of 70.2 g, followed by hybrids BWR-5 × 857 and BWR 15 × 674 (Table 4).

[a]Total soluble solids

This study helped to establish the possibility of developing F_1 hybrids resistant to bacterial wilt and suitable for processing. In order to improve the processing qualities of hybrids further, it is essential to enhance the specific attributes in potential bacterial wilt resistant parental lines.

Studies on Genetic Resistance to Bacterial Wilt and Root-knot Nematode in Tomato

S. Nirmaladevi and S.K. Tikoo*

Abstract

Bacterial wilt caused by *Pseudomonas solanacearum* and root-knot nematode caused by *Meloidogyne incognita* are major factors limiting tomato production in the areas where it is traditionally grown. Development of resistant varieties is economical and an environmentally safe means of control. This study: (i) examined the inheritance of combined resistance to bacterial wilt and root-knot nematode; (ii) evaluated the interaction of these soilborne pathogens on the resistant genes present in the host genotype; and (iii) identified a broad spectrum of resistant sources among known lines/varieties. The results showed that the F_1 of parents with dominant sources of resistance to wilt and root-knot nematode were resistant to both the diseases in the field. The interaction between pathogens has modified the genetic ratios of the crosses. A significant correlation between ooze and gall indices indicated that the nematodes predisposed the plants to bacterial wilt. The lines selected for resistance to bacterial wilt at Hessaraghata have shown differential response to isolates of *P. solanacearum* from Maharashtra, Kerala and Chethalli. The best F_1 hybrids for fresh market were BWR 1 × Rossol, 83 BWR 12-2 × IHR 998, 83 BWR 120 × Patriot and MITA 668 × 83 BWR 120.

BACTERIAL wilt caused by *Pseudomonas solanacearum* E.F. Smith is an important disease of solanaceous vegetables in most of the States of India (Rao 1976). Losses in tomato yields due to the disease have been reported to be as high as 90% (Kishun 1985). Genetic resistance to wilt was located in some lines of tomato introduced from Hawaii and Taiwan. Root-knot nematode, *Meloidogyne incognita*, is also recognised as a major pest of tomato in tropical countries and is reported to cause yield losses up to 61% (Naganathan 1984). Use of resistant plants enables the grower to control root-knot without increasing the cost of production.

While genetic resistance to bacterial wilt has been known to breakdown in certain cases associated with root-knot nematode infection, the genetics of interaction of *P. solanacearum* and root-knot nematode on bacterial wilt resistant varieties has not been studied. In addition, Rao et al. (1975) reported that, of the 23 varieties and lines (from USA and Philippines) previously considered resistant to *P. solanacearum*, only CRA 66 Sel A was resistant at Hessaraghata both under artificial inoculation and field tests. This indicated the possibility of differential pathogenicity to different geographic isolates. Therefore, the present study was undertaken to evaluate the inheritance of combined resistance to bacterial wilt and root-knot nematode, to study the interaction of these soilborne pathogens on the resistant genes present in the host and to identify a source of broad-spectrum resistance to bacterial wilt.

*Indian Institute of Horticulture Research, Hessaraghata Lake, PO Bangalore 560 089, India.

Materials and Methods

Selection of parents and hybridisation

Six lines resistant to bacterial wilt and 12 cultivars/lines resistant to root-knot nematode were used (Table 1). Each of the six bacterial wilt resistant (BWR) lines were crossed with all the nematode resistant (NR) lines to obtain F_1s to be studied for yield and reaction to the diseases.

Evaluation of parents and F_1s in infested field soil

The parents and F_1s were planted in the bacterial wilt infested plot (10^8 cfu/g of soil) in a randomised block design. At the time of planting, 100 g of nematode-infested soil containing about 1000 *M. incognita* larvae were put in the planting holes. The plants were rated for survival, ooze and gall indices, and yield. Three F_1 hybrids resistant to both pathogens, two F_1s resistant to

nematodes and susceptible to *P. solanacearum*, and one F_1 resistant to *P. solanacearum* and susceptible to nematodes were selected and selfed to obtain the F_2 population, then backcrossed with their respective male and female parents to obtain backcross populations (B_1 and B_2) for further studies.

Evaluation of six generations for different characters

The parents, F_1s, F_2s, B_1s and B_2s were planted in field-infested soil and rated for survival, ooze and gall indices and yield. Based on reactions to bacterial wilt and root-knot nematode, plants were grouped into four categories, viz.: resistant to nematode and bacteria (NRBR); resistant to nematode and susceptible to bacteria (NRBS); susceptible to nematode and resistant to bacteria (NSBR); and susceptible to both (NSBS). The data were statistically analysed as suggested by Panse and Sukhatme (1985).

Results and Discussion

Performance of parental and F_1 lines

Survival of plants. The BWR lines had significantly higher survival rates than the nematode-resistant lines in the infested field (Table 2). The survival of BWR 1 and CRA 66 Sel A was less than previously reported (Tikoo et al. 1989), probably because the nematodes had predisposed these lines to wilt. Such predisposition has been reported earlier by Sellam et al. (1980). Among the nematode-resistant lines, MITA 668, 84 BWR 30 and 84 BWR 32 had higher survival rates because MITA 668 was originally introduced as a bacterial wilt resistant line and the other two were derivatives of MITA 668.

The F_1 hybrids of 83 BWR 12-2, BWR 1 and BWR 5 were resistant to wilt, indicating the dominant source of resistance in these lines (Table 2). There were susceptible, moderately resistant and resistant lines among the F_1s of 83 BWR 90, probably because this line was a derivative of CRA 66 Sel A, reported to be a recessive source of resistance to wilt. The dominant source of resistance to wilt in 83 BWR 120 was indicated by the resistance of its F_1s to wilt.

Ooze index. The ooze index in BWR lines was more than 1.0, indicating that the bacteria were able to multiply in these lines without killing the plants (Table 2). The ooze indices of NR lines were significantly higher than those of BWR lines in a manner directly proportional to their susceptibility to wilt (Table 2). The ooze indices of the F_1 hybrids of 83 BWR 12-2, BWR 1 and BWR 5 were more than 1.0 but they survived in the field indicating that the F_1s are also capable of withstanding bacterial multiplication. The ooze indices of the F_1s of CRA 66 Sel A also indicated susceptibility to wilt, but these plants were susceptible only after 100 days, probably because of delayed expression of disease.

Gall index. In the field infested with both pathogens, the NR lines remained resistant to nematodes as shown by the gall index 1 (Table 2). On the contrary, the BWR lines were highly susceptible to nematodes. In general, the F_1 hybrids of BWR lines with NR lines were resistant to nematodes (Table 2). However, the F_1 hybrid of BWR lines with MITA 668 was susceptible to nematodes. MITA 668 has been reported (Tikoo and Anand 1986) to have a recessive source of resistance to nematodes. The F_1 hybrids of BWR lines with 84 BWR 30 and 84 BWR 32 were only moderately resistant to nematodes, indicating that resistance is not completely dominant in this line, probably because they were derivatives of MITA 668.

Genetics of combined resistance to bacterial wilt and root-knot nematode

The inheritance pattern of combined resistance studied in six crosses did not fit the expected 9:3:3:1 ratio in the F_2s (Table 3). F_2 populations of BWR 1 crosses had higher than expected numbers of plants in NSBS class and there was perfect fit for a 9:3:4 ratio because of the shift in numbers from NSBR class to NSBS class due to susceptibility to nematodes which increased wilt. This indicated that simultaneous interaction of the two pathogens has modified the host response. The X^2 value was highly significant in the B_1 population whereas it was not significant in the B_2s. These results confirmed the modification of genetic ratios as a result of lack of independent assortment of the two genes or, as reported by Sidhu (1984), parasitic epistasis.

The F_2, B_1 and B_2 population of CRA 66 Sel A hybrids with Rossol and Patriot had significantly higher X^2 values, indicating that the pattern of segregation did not fit any Mendelian ratio. This could be due to the

polygenic system that governs resistance in the CRA 66 Sel A. The F_1s were also susceptible to wilt, supporting the results of earlier work (Tikoo et al. 1989).

The significant X^2 deviation in the F_2 of MITA 668 × 83 BWR 120 was due to increased susceptibility to wilt as a result of infestation by nematodes (Table 3). This confirmed the monogenic recessive source of resistance to nematodes in MITA 668 (Tikoo and Anand 1986). The modification of genetic ratios as a result of increased susceptibility to wilt was further confirmed (Figs 1, 2). The segregation pattern of ooze index was not independent, whereas that of gall index was.

Correlation studies

The survival of plants after 80 days was highly and significantly correlated with that after 100 days (Table 4). The percentage survival of plants reached a plateau by 80 days and it appears that resistant plants can be selected after 80 days. This will enable the breeder to select resistant plants and to plan his backcross breeding program without waiting till the end of the crop. The phenomenon of predisposition by nematodes was reported by Sidhu and Webster (1974) in relationship to *Fusarium* wilt and by Sellam et al. (1980) and Napiere (1980) in nematode-bacteria complex.

Negative correlation between survival of plants after 100 days and gall and ooze indices indicates that both root-knot nematode and bacterial infection reduce the survival rates of plants (Table 4). This phenomenon has been reported earlier by Goth et al. (1983) and Routarary et al. (1986).

Response of BWR lines to four isolates of *P. solanacearum*

The reactions of four BWR lines—BWR 1, CRA 66 Sel A, 83 BWR 90 and 83 BWR 120—to four isolates of *P. solanacearum* from Hessaraghata and Chethalli (Karnataka), Dapoli (Maharashtra) and Thrissur (Kerala) were studied. Significant differences in response were observed between the four isolates (Table 5). The Maharashtra and Kerala isolates proved to be more pathogenic.

Fruit yield

The number of fruits per plant, yield per plant and average fruit weight of certain BWR lines and their F_1s differed significantly between seasons and lines. The F_1

hybrids BWR 1 × Rossol, 83 BWR 12-2 × IHR 998, 83 BWR 120 × Patriot and MITA 668 × 83 BWR 120 were judged best for fresh fruit for market and were also resistant to bacterial wilt.

The present study indicates that combined resistance to bacterial wilt and root-knot nematode is digenically inherited and that the resistance in bacterial wilt resistant genotypes changes following root-knot nematode infestation. Selection of plants in the segregating population and backcross breeding will help to evolve tomato varieties resistant to bacterial wilt and root-knot nematodes.

DNA Genetic Marker Mapping of Genes for Bacterial Wilt Resistance in Tomato

S.R. Aarons, D. Danesh and N.D.Young*

Abstract

To locate genes associated with resistance to bacterial wilt (BW; *Pseudomonas solanacearum*) in tomato, an F_2 population segregating for resistance was analysed using DNA genetic markers. The population was derived from a cross between a resistant tomato genotype, L285, and a susceptible cultivar, CLN286. Because this cross is intraspecific in nature and therefore low in DNA sequence polymorphism, 100 clones from the established tomato molecular map were surveyed with 30 restriction enzymes to find a total of 46 restriction fragment length polymorphisms (RFLPs). Additionally, seven random amplified polymorphic DNA markers were added to the map. At 10 days after inoculation, two genomic regions were found to be associated with BW resistance. One of the putative resistance loci, located on a linkage group consisting of RFLPs known to reside on chromosome 6 of tomato, was significantly ($p = 0.0004$) correlated with BW resistance. At 14 days after inoculation, three genomic regions were correlated with BW resistance. These included the region on chromosome 6, plus two others on linkage groups seven and 10. The region on linkage group 7 was unusual in that the allele from the susceptible parent (CLN286) was the one associated with higher levels of resistance in the F_2. Together, the three putative resistance loci explained 49% of the total variation in BW resistance in the F_2. Five cases of significant gene × gene interactions were also observed.

BACTERIAL wilt (BW) is a major disease of many important crops, including several in the Solanaceae. The causal agent, *Pseudomonas solanacearum*, invades the vascular system of the host and grows *in planta*, restricting transpiration of water. Wilting occurs, often accompanied by poor plant growth and even death. Although biological control of *P. solanacearum* has been recommended (Trigalet and Trigalet-Demery 1990), the best method of control known is the use of BW-resistant lines (Opeña et al. 1990). In the past, resistance to BW in tomato has generally not been stably maintained [Opeña and Hartman, Asian Vegetable Research and Development Center (AVRDC), Taiwan, pers. comm.]. However, a landrace of *Lycopersicon esculentum* known as line L285 has moderately durable resistance (Opeña and Hartman, AVRDC, pers. comm.). The resistance is thought to be polygenic, as indicated by the pattern of the resistance among F_2 progeny, although the number of genes involved and their contribution are unknown.

*Department of Plant Pathology, University of Minnesota, St Paul, MN 55108, USA.

Restriction fragment length polymorphisms (RFLPs) and, more recently, random amplification of polymorphic DNA (RAPDs), have been used to link DNA genetic markers to disease resistance in tomato (Behare et al. 1991; Messeguer et al. 1991; Martin et al. 1991; Sarfatti et al. 1989; Young et al. 1988). Much of this success is due to the availability of a well-saturated RFLP map for tomato (Tanksley et al. 1992), one of the best among higher plants. Using DNA markers, breeding for complex characters such as BW resistance should be much more straightforward. In particular, retaining resistance loci while simultaneously selecting against unwanted characters from a donor parent should be feasible.

To locate the genes that underlie BW resistance in L285, we have initiated a mapping effort based on RFLP and RAPD markers. In this preliminary report, we describe experiments in which 53 DNA markers spread throughout the tomato genome were used to locate regions associated with BW resistance. The results indicate that at least four genomic regions contain putative loci for BW resistance, including one region that plays a major role in the response.

Materials and Methods

Plant material

Bacterial wilt resistant L285, a cerasiforme-type of tomato, was crossed with a cultivated but susceptible line, CLN286BC1F_2-25-14-7 (henceforth called CLN286), at AVRDC and increased to produce the F_2 progeny. The parents and 71 F_2 progeny were grown in a soil:vermiculite:peat (1:1:1) mix in the greenhouse at the University of Minnesota in St Paul, Minnesota. Leaves were collected from each plant for DNA extraction as described below. Three to four cuttings of each plant were then made for inoculation with *P. solanacearum* and disease scoring. Cuttings of lateral branches were rooted and transplanted into the soil mix and grown for 7 days prior to inoculation.

Disease scoring

P. solanacearum strain UW364, a Race 1, Biovar 4 isolated from tomato in China (Cook et al. 1989), was used in inoculation tests. Cells were grown on casamino acid, peptone, and glucose (CPG) medium for 48 hours, washed into sterile distilled water, and diluted to give an optical density (Å600) of 0.100 (10^8 cells per mL). Cuttings of the parents and progeny were inoculated by placing 15 uL of the inoculum in the third leaf axil from the top and passing a needle through the drop into the stem of the plant. Control plants were inoculated at the same time with 15 uL of sterile distilled water. Virulence of the pathogen was determined by hypersensitivity tests on *Nicotiana tabacum*. Plants were maintained in the greenhouse at 28–30°C and preliminary disease symptoms scored 7 days after inoculation (DAI), and then again on 10 and 14 DAI. On day 14 all plants that were not wilted or dead were re-inoculated to prevent escapes, and plants were scored again 7 days after the second inoculation. Symptoms were indexed on a scale of 1 (no symptoms) to 4 (severe wilting and death).

RFLP analysis

DNA extracts from the parents were surveyed to identify polymorphic clones. Tomato DNA was extracted using the protocol of Dellaporta et al. (1983) with minor modifications. The extracted DNA was digested with 1 of 30 restriction enzymes, electrophoresed on 1% agarose gels, and Southern blotted onto Hybond N+ (Amersham, Inc.) membranes (Southern 1975). One hundred tomato genomic clones kindly provided by Dr S. Tanksley (Department of Plant Breeding, Cornell University, Ithaca, NY) were amplified by polymerase chain reaction before random hexamer labelling (Feinberg and Vogelstein 1983) with a-32P-dCTP. Labelled clones were first hybridised to filters containing restriction enzyme digested parental DNA in order to identify band length polymorphisms. Each polymorphic clone was then hybridised to filters containing parental and F_2 DNA digested with the appropriate restriction enzyme for that clone.

RAPD analysis

Randomly amplified DNA polymorphisms between L285 and CLN286 and among the F_2 progeny were identified using DNA extracted as described above. For each reaction, 2 ng of DNA was amplified with 15 ng of a 10-mer primer (Operon) and 1.75U Taq polymerase (Promega) as described by Williams et al. (1990). A Coy Tempcycler (model 50) was used for 45 cycles of 1 minute at 94°C, 1 minute at 35°C and 2 minutes at 72°C. Amplified fragments were electrophoresed in 1.4% agarose.

Linkage analysis

Mapmaker software (Lander et al. 1987) was used to construct a linkage map for the L285 × CLN286 cross, based on segregation data in the F_2 for each polymorphic marker. Linkage was inferred with a minimum LOD (log of the odds ratio) score of 2.5. DNA markers associated with BW resistance were then identified using the statistical software, Statview-II (Abacus Concepts). In the analysis, both simple regression and single factor analysis of variance (ANOVA) were utilised with a significance level of $p < 0.01$. Two-factor ANOVA was also performed between putative BW resistance loci and the remaining DNA markers on the genetic map to uncover possible gene × gene interactions. In this analysis, a significance level of 0.01 was also used.

Results and Discussion

Genetic map of L285 × CLN286 cross

Because of the intraspecific nature of the cross between the parents, DNA polymorphism was low. Initially, 10 enzymes (BamHI, BstNI, DraI, EcoRI, EcoRV, HaeIII, HindIII, RsaI, TaqI, XbaI) were used to survey the clones, of which only 30% were polymorphic. A second set of 10 enzymes (AseI, BclI, BsaBI, DpnI, HinfI, HhaI, MspI, NdeI, NsiI, ScaI) was then used to prepare filters, which were probed together with filters from the first 10 enzymes. The rate of polymorphism almost doubled to 53%. The remaining non-polymorphic clones were then hybridised to filters made with a third set of enzymes (AflII, AluI, BanI, BglII, BstEII, BstXI, KpnI, VspI, SspI, XmnI) and an additional eight polymorphic clones were identified. In a report by Miller and Tanksley (1990), the percent polymorphism between cultivated tomato and a cerasiforme genotype was low (41% with 5 enzymes); our results indicated that doubling the number of restriction

enzymes surveyed led to a twofold increase in polymorphisms. Nevertheless, 10 additional restriction enzymes increased the level of polymorphism only slightly.

Linkage analysis of the polymorphic clones produced the map shown in Figure 1. Additional markers were added using RAPDs. The linkage groups generally agreed with the chromosomes of the published tomato map (Tanksley et al. 1992). However, several clones mapped to positions different from those previously reported, presumably because we mapped different segregating bands for those clones. This is particularly striking for the linkage group tenatively assigned as chromosome 7. Because of this and other discrepancies, the chromosome assignments in this report should be considered tentative. Nonetheless, any statistical associations between DNA genetic markers and BW resistance would be unaffected by discrepancies in the assignment of linkage groups.

Some linkage groups were also poorly populated, with groups 3, 4, 5, and 8 having only a single marker. Still other linkage groups (1, 2, 6, and 11) consisted of two linkage blocks unlinked to one another, but inferred to be on the same chromosome based on the map of Tanksley et al. (1992). For all of these reasons, the saturation of DNA markers throughout the tomato genome was far from complete in this study and it is possible that some resistance loci have been missed.

Disease scoring

Disease indices of the resistant and susceptible parents were 1.0 and 4.0, respectively (data not shown), while the majority of the F_2 fell between these values (Fig. 2). Many F_2 progeny showed a score of two, with the distribution slightly skewed toward resistance. The continuous nature of the disease severity in the F_2 strongly indicated that multiple genes were involved in the response. Disease index of the F_2 individuals changed only slightly between 10 and 14 days, although sufficiently to uncover different putative resistance loci (see next section).

Map locations of putative BW resistance loci

Statistical analysis of BW disease index and DNA marker scores indicated that two genomic regions were associated with resistance at 10 DAI, one residing on

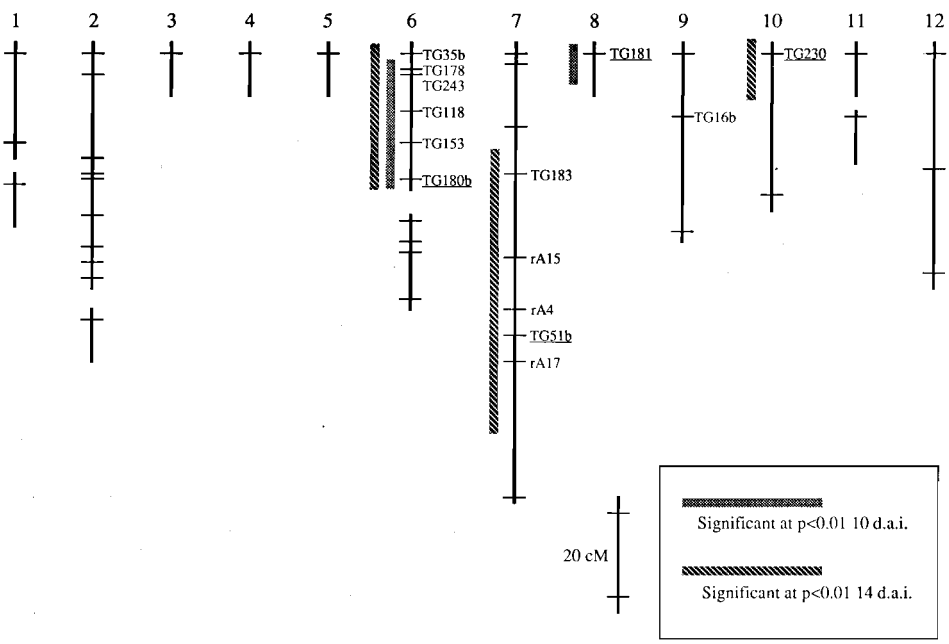

Fig. 1. Linkage map of tomato, consisting of 46 RFLP and 7 RAPD markers. Marker positions are based on segregation in the L285 × CLN286 F_2 population, as estimated by the Mapmaker (Lander et al. 1987) program with a minimum LOD of 2.5. Linkage groups were tentatively assigned to 'chromosomes' based on RFLPs common to the map of Tanksley et al. (1992). Those markers that map to a locus different than reported by Tanksley et al. (1992) are noted by the letter 'b' at the end of the marker name. Genomic regions showing significant association with BW resistance at 10 and 14 days after inoculation are highlighted with a bar beside each of the regions. DNA markers showing correlation are noted, and the locus with the highest association is underlined. DNA marker TG16b, which was found to be significant only in terms of gene × gene interaction, is also noted.

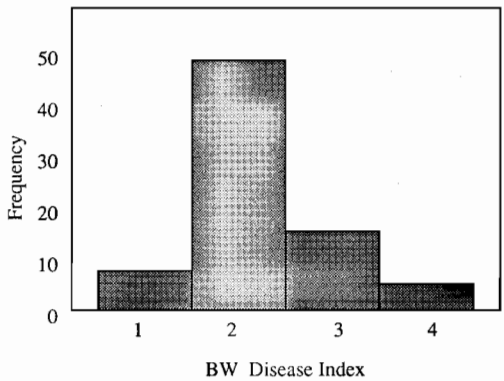

Fig. 2. Frequency distribution of bacterial wilt index scores 14 days after inoculation. Three or four cuttings from each of 71 F_2 plants were inoculated as described in the material and methods section and scored for BW disease 14 days later. Each group of cuttings was scored on a scale from 1 (no disease) to 4 (severe wilting and/or death).

linkage group 6 and another on linkage group 8 (Table 1, Fig. 1). The region on linkage group 6 was particularly significant, with five contiguous markers found to be significant and one (TG180) significant at the 0.0004 level (based on regression). Approximately 17% of the variation in BW reaction could be explained by this marker. Individuals homozygous for the TG180 allele from L285 were 0.63 disease index units lower than homozygotes for the CLN286 allele.

In contrast, the genomic region on linkage group 8 (TG181) was only barely significant (p=0.0089) and had a much smaller impact on BW disease response. The effect of this putative resistance locus was also unusual in that the allele from CLN286 was associated with resistance, even though CLN286 is, itself, more susceptible to BW disease. In this way, the putative resistance locus near TG181 resembled the one on linkage group 7 described below.

By 14 DAI, three genomic regions were found to have significant associations with BW disease, one each on linkage groups 6, 7, and 10 (Table 1, Fig. 1). Results at 21 DAI, 7 days after surviving plants had been reinoculated with *P. solanacearum*, gave essentially the same results as observed at 14 DAI and are not shown. At 14 DAI, the putative locus previously observed on linkage group 8 was no longer considered significant, having a p-value of 0.0132. By contrast, the association between BW response and the putative resistance locus near TG180 on linkage group 6 had grown much stronger, with several contiguous markers now showing correlation at the p=0.0001 level. The proportion of variation explained by marker TG180 increased to 32% and the difference in disease index between individuals homozygous for the L285 allele compared to those homozygous for CLN286 had also increased to 0.98 units.

On linkage group 10, a single locus (TG230) was found to be associated with BW response. This marker just missed being counted as significant at 10 DAI, having a significance level of 0.0197 at that time. By 14 DAI, the significance level was p=0.0033 and approximately 12% of the variation in disease could be explained by this locus. Homozygotes for the L285 allele at TG230 were more than 0.6 disease units lower than homozygotes for CLN286.

The effect of the putative resistance locus on linkage group 7 at 14 DAI resembled the one near TG181 on linkage group 8 at 10 DAI and differed fundamentally from the putative resistance loci near TG180 and TG230. In the case of the putative resistance locus on linkage group 7, the allele from CLN286 was the one associated with resistance. Five contiguous DNA

Table 1. Marker loci showing significant relationship to bacterial wilt resistance from rating taken at 10 or 14 days after inoculation (DAI).

Marker	Linkage group	DAI	R-squared	Probability (regression	Probability (ANOVA)	Type of effect[a]	Phenotypic effect[b]
TG180b	6	10	0.169	0.0004	0.0002	Dom(285)	(–)0.63

[a]Type of gene action, either additive (Add), recessive (Rec), or dominant (Dom). Numbers in paretheses indicate the parent (L285, "285 and CLN286, "286) carrying the allele that confers higher levels of resistance to BW.
[b]Difference in BW disease index between L285 homozygotes compared to CLN286 homozygotes.
[c]Type of gene action could not be inferred.
[d]Not significant.

markers were found to be correlated to BW response and two of the markers (TG51 and rA04) were significant at p=0.0002. Individuals that were homozygous for the CLN286 allele at TG51 were approximately 0.66 disease units lower than homozygotes for the L285 allele.

Interactions among putative BW resistance loci

In a genetically complex type of disease resistance, such as observed in the cross between L285 and CLN286, primary gene effects may be affected by interactions among resistance loci. To uncover putative gene × gene interactions associated with BW resistance, two factor ANOVA was performed between primary loci (identified by regression and/or single factor ANOVA) and the remaining loci on the molecular map. This analysis identified five significant interactions at 14 DAI, three involving the putative resistance locus on linkage group 6 and two involving the putative locus on linkage group 7 (Table 2).

Several interesting trends could be observed from the analysis of gene × gene interactions. First, the putative resistance locus on linkage group 6 interacted with two of the other genomic regions that had previously been found to be individually significant by single factor ANOVA (TG183 on linkage group 7 and TG230 on linkage group 10). Likewise, the putative resistance locus on linkage group 7 interacted with a marker on linkage group 6 (TG35b) that was also found to be significant by itself. Moreover, the putative resistance loci on both linkage groups 6 and 7 interacted with the same locus on linkage group 9 (TG16b), a marker that was not individually correlated to BW resistance.

Table 2. Loci showing significant gene × gene interactions.

Primary locus	Linkage group	Interacting locus	Linkage group	Probability (ANOVA)
TG51b	7	TG35	6	0.0068
TG51b	7	TG16b	9	0.0076
TG118	6	TG183	7	0.0052
TG118	6	TG16b	9	0.0008
TG118	6	TG230	10	0.0022

Applications of DNA markers linked to BW resistance loci

The primary goal of this study was to map putative resistance loci for BW resistance. However, besides mapping putative resistance loci, DNA marker analysis also enables the selection of F_2 plants suitable for use in breeding and genetic analysis. F_2 plants that have retained putative resistance loci from L285, and at the same time carry a minimum of L285 DNA elsewhere in the genome, can now be identified with DNA markers. In the process, individuals with crossovers near the putative resistance loci can also be pinpointed. This should be especially significant in the case of breeding BW resistance from L285, because resistance has previously been associated with small fruit size (Opeña and Hartman, AVRDC, pers. comm.).

At the same time, the contribution of different resistance loci can be studied individually, as it is now possible to select F_2 plants that can be used to develop lines that carry only one or a few of the putative resistance loci. Considering the very different types of gene action observed for the different resistance loci uncovered in this study (such as the resistance locus on linkage group 6 versus the locus on linkage group 7), this type of genetic dissection should be especially informative.

Finally, using DNA markers near resistance loci to select lines with tightly linked crossover may be useful for purposes other than minimising linkage drag. In particular, crossover located near genes of interest can be used as a basis for fine-structure mapping near those genes. Considering the fact that the putative resistance locus on linkage group 6 controls a very large fraction of the variation in BW response (greater than 30%), fine structure mapping around this locus may provide a basis for physical mapping and eventual gene cloning based on chromosome walking (Young 1990). Although this type of research is still far in the future, the fact that tomato has desirable features such as a comprehensive yeast artificial chromosome library (S. Tanksley, pers. comm.) and high efficiency plant transformation (McCormick et al. 1986) may make it possible to clone some of the resistance loci uncovered in this study. If so, the major BW resistance locus of L285 may then be one of the first quantitative resistance genes to be cloned at the molecular level.

Acknowledgments

We would like to thank Dr Steven Tanksley for providing tomato genomic clones and Drs Luis Sequeira and Elizabeth Barlow for providing strains of *Psuedomonas solanacearum*. We would also like to thank Drs Romeo Opeña and Glen Hartman for kindly providing the F_2 population used in this study. This research was supported by the US-AID/USDA/CSRS Research Grants Program grant AID/DAN-4136-G-00-1018-00. This paper is published as contribution 20240 of the series of the Minnesota Agricultural Experiment Station.

Mapping of Bacterial Wilt Resistance Genes in Tomato Variety Hawaii 7996

P. Thoquet, S. Stephens and N. Grimsley*

Abstract

In order to map the resistance genes, a cross between two *Lycopersicon esculentum* varieties, Floradel (susceptible) and Hawaii 7996 (resistant), was used. We plan to compare segregation of resistance in laboratory tests with that in a field trial (in collaboration with INRA, Guadeloupe). These varieties show little polymorphism, making RFLP analysis difficult. However, using RAPD markers it should be possible to find polymorphisms relatively quickly. Since resistance in Hawaii lines was originally introgressed from *L. pimpinellifolium*, it is possible that many polymorphisms will be linked to the genes of interest.

TOMATO was chosen to study naturally occurring mechanisms of resistance to bacterial wilt. Most tomato varieties are susceptible but there are several lines which have been selected for resistance. The genetic basis for the resistance is not known, but there is evidence that several genes are involved. There is also evidence that one major effect may map to chromosome 6, since the character is difficult to combine with nematode resistance (Gilbert and McGuire 1956) or the marker *sp* (Acosta et al. 1964). A fruit-size effect may also be linked (McGuire 1960). Using crosses between resistant varieties and susceptible varieties or wild species of tomato, we will map the resistance gene(s) using several mapped RFLP markers (S. Tanksley, pers. comm.) and RAPD markers that are being developed in our laboratory.

Bulked segregant analysis (Michelmore et al. 1992) will be used to identify RAPD markers close to resistance genes. In this analysis, DNA from susceptible F_2 plants will be bulked, as will DBA from resistant F_2 plants. RAPDs which are only found in one of these two groups will be linked to the gene(s) for sensitivity or resistance, respectively. Other RAPD markers that are unlined to these genes will be found in both groups. Polymorphisms in which a RAPD band is linked to resistance in Hawaii 7996 or susceptible Floradel can be transformed into RFLP markers by cloning the band and placing on the map obtained from the crosses Hawaii 7996 × *L. pennellii*.

We will attempt to map RAPD polymorphisms using existing RFL probes on the Floradel × Hawaii 7996 F_2. However, in case there is insufficient polymorphism an F_2 population from the cross Hawaii 7996 × *L. pennelii* LA716 is also available to place the new RAPD markers on the existing tomato genetic map using a set of 24 RFLP markers received from S. Tanksley. This population will also be used for the mapping of various cDNA clones from genes known to be expressed in the course of infection of tobacco by *P. solanacearum* (Marco et al. 1990). *L. pennellii* was reproducibly sensitive to bacterial wilt, so this population is unsuitable for direct mapping of the resistance genes.

Development of an In Vivo Complementation System for Identification of Plant Genes using Yeast Artificial Chromosomes (YACS)

A.B. Bonnema*, R. Peytavi*, R.A.J. Van Daelen†, P. Zabel† and N. Grimsley*

Abstract

Map-based cloning of genes demands the use of vectors containing large inserts of foreign DNA, such as yeast artificial chromosomes (YACs). Once the region of the genome containing the locus of interest (for example, a disease resistance gene) has been cloned, final proof of the presence of the gene requires in vivo complementation tests. However, there are at present no techniques to allow the introduction of YACs into plants. We are developing a YAC–plant transformation system. The plant selectable marker genes for hygromycin resistance and kanamycin resistance were introduced into existing YAC vectors. A partial tomato YAC library was constructed in these newly constructed YAC vectors. Techniques to transfer these YACs to plants, by yeast spheroplast–protoplast fusion or via direct DNA transfer to plant protoplasts are being developed.

ONE long-term goal in plant biotechnology is to clone the individual genes responsible for controlling agronomically important characters, since very specific characters could then be introduced into plants in a controlled way within a relatively short space of time, by transformation and regeneration of plants in culture. Map-based cloning and cDNA cloning techniques will permit the isolation of genes of interest, but equally important is the development of plant transformation technologies.

The recent development of yeast artificial chromosomes (YACs) allows cloning of fragments of DNA 100–500 kilobases (kb) in size, a factor of 10 larger than fragments cloned in conventional vectors (Burke et al. 1987; Schlessinger 1990), reducing the number of clones necessary for construction of a representative gene library, facilitating 'chromosome walking' and permitting cloning of large eukaryotic genes such as *Drosophila bithorax* (320 kb, Karch et al. 1985) and factor VIII (190 kb, Gitschier et al. 1984). Genes of similar size are most likely present in plant cells. YAC vectors exist with replicons and selectable markers for *E. coli* or yeast, and thus can be propagated in either of these organisms as plasmids or artificial chromosomes, respectively.

Genomic libraries in YACs have been constructed for a variety of organisms. These libraries can be used to screen for genes of interest with known genetic map position using tightly linked molecular markers as probes. Once the chromosomal region spanning the gene of interest has been cloned, final identification of the gene depends on successful in vivo complementation tests of plants deficient for the gene function. This remains an enormous task when only the genetic map position of the gene is known, since only relatively small DNA fragments can be transferred to plants using conventional gene-transfer techniques. Functional testing currently requires subcloning fragments of an existing YAC clone, and this has the following disadvantages: (1) a series of closely linked YAC clones would be difficult to test, as too much work in physical mapping, subcloning, and plant transformation would be required; (2) large genes or gene complexes would be lost; and (3) prokaryotic vectors may not tolerate certain kinds of DNA structures found in eukaryotes.

†Department of Molecular Biology, Agricultural University, Dreijenlaan 3, 6703HA Wageningen, The Netherlands.

The development of a YAC–plant cell complementation system would greatly facilitate this task. Such a system would also permit in vivo complementation tests of large plant genes, such as those with many exons or distant regulatory sequences.

Recently, YACs containing long stretches of cloned DNA have been reintroduced into mammalian cells. Techniques used to transfer the YAC DNA into mammalian cells are both fusion of the mammalian cells with the yeast spheroplasts (Gnirke and Huxley 1991; Huxley et al. 1991; Pachnis et al. 1990), and direct transfer of the naked DNA to mammalian cells (Eliceiri et al. 1991; Fernandez-Luna et al. 1991; Gnirke and Huxley 1991; Strauss and Jaenisch 1992). Suitable selectable markers for transformation of mammalian cells were introduced into existing human YAC clones by homologous recombination in yeast (Pachnis et al. 1990). Auxotrophic mammalian cells have been complemented in vivo with YACs carrying the corresponding cloned genes (Eliceiri et al. 1991; Gnirke and Huxley 1991; Huxley et al. 1991). YACs were stably integrated in mammalian genomes, the integrated DNA was not rearranged, and cloned genes were expressed, indicating that YACs can conserve the structure of genomic DNA (Pachnis et al. 1990).

Currently available YAC vectors do not contain plant-selectable markers, rendering them useless for plant transformation. The development of YAC vectors containing plant-selectable markers, and the development of techniques to transform plants with these YACs containing large stretches of cloned DNA, will be essential tools for future plant biotechnology. Introduction of a YAC carrying plant DNA into plant cells has not been described, although protoplasts can take up and integrate naked DNA into their nuclear genomes (Negrutiu et al. 1987) and can be fused with protoplasts of other species to generate somatic hybrids (Bonnema et al. 1991).

For the development of the YAC–plant transformation system, we work with a heterologous system to be able to follow the fate of the transforming DNA. A partial tomato YAC library has been constructed in YAC vectors containing plant selectable markers, and this library has been screened for the presence of a well-characterised tomato specific *Hind*III repeat. The tomato genome contains about 75000 copies of this tomato specific *Hind*III repeat, which is dispersed over the genome and present on all chromosomes (Zabel et al. 1985). The sequence of this repeat is known. Techniques to transfer these YACs to plants are being developed, using a haploid *Nicotiana plumbaginifolia* and *Nicotiana tabacum* 'SR-1' as acceptor species. Their genomes contain no sequences hybridising to the tomato specific *Hind*III repeat, which facilitates the analysis of the fate of the tomato YAC in the transformed plant. Protoplast isolation and regeneration techniques are well-developed for these species. They are therefore good model systems to use before attempting complementation in tomato.

Materials and Methods

Growth of bacterial strains and in vitro manipulation of DNA were done according to standard protocols (Sambrook et al. 1989), except where otherwise stated. Yeast was handled according to standard protocols (Guthrie and Fink 1991).

Yeast strains

The following three yeast strains were used: (i) AB1380: haploid, MAT, U, ura3, trp1, ade2-1, can1-100, lys2-1, his5; (ii) YPH252: haploid, MAT, ura3-52, lys2-801 amber, ade2101 ochre, trp1-D1, his3-D200, leu2D1; and (iii) YPH274 (Mat /Mata; ura3-52; lys2-801/amber; ade2-101/ochre; trp- 1; his3- 200; leu2 1)

Construction of YAC vectors

pYACAB1 and pYACAB2. The *Xho*I site of pYACRC (Burke et al. 1987), bordering the left TEL sequence, was changed to an *Eco*RI site by linker insertion. Plasmid pHP23b (J. Paszkowsky, pers. comm.) containing the NPTII gene under the control of the CaMV 35S promotor and terminator, was modified by removing the *Sal*I and *Bam*HI restriction sites (by digestion, filling-in [Klenow], and blunt-end ligation). The 1.7 kb *Eco*RI fragment containing the NPTII gene, was ligated into the newly created *Eco*RI site of pYACRC, so creating pYACAB1 (NPTII gene transcribed towards the centromere) and pYACAB2 (NPTII gene transcribed towards the TEL sequence) (Fig. 1).

pJAB1 and pJAB2. The plasmid pGL2 contains the hygromycin gene (HPH), under control of the CaMV 35S promotor and terminator constructed in plasmid pDH51 (Gritz and Davies 1983). Plasmid pGZ5 is derived from plasmid pGL2 by inserting *Xho*I sites, so that the hygromycin (HPH) gene can be recovered as a 1.5 kb *Xho*I fragment. The BamHI and SalI restriction sites were removed from the HPH gene, and the 1.5 kb XhoI fragment containing the HPH gene, was ligated into the *Sal*I sites of pUC7. The HPH gene was then excised as a 1.5 kb *Bam*HI fragment, and ligated into the unique *Bam*HI site of polylinker 2 of the vector pJS97 (Shero et al. 1991), to create pJAB1 (HPH gene transcribed towards the TEL sequences) and pJAB2 (HPH gene transcribed away from the TEL sequences).

pJAB4. The 1.7 kb fragment of modified (as above) pHP23b containing the NPTII gene was Klenow filled in, and ligated into the *Sma*I site of vector pV125 (a pUC series derivative containing an altered polylinker)

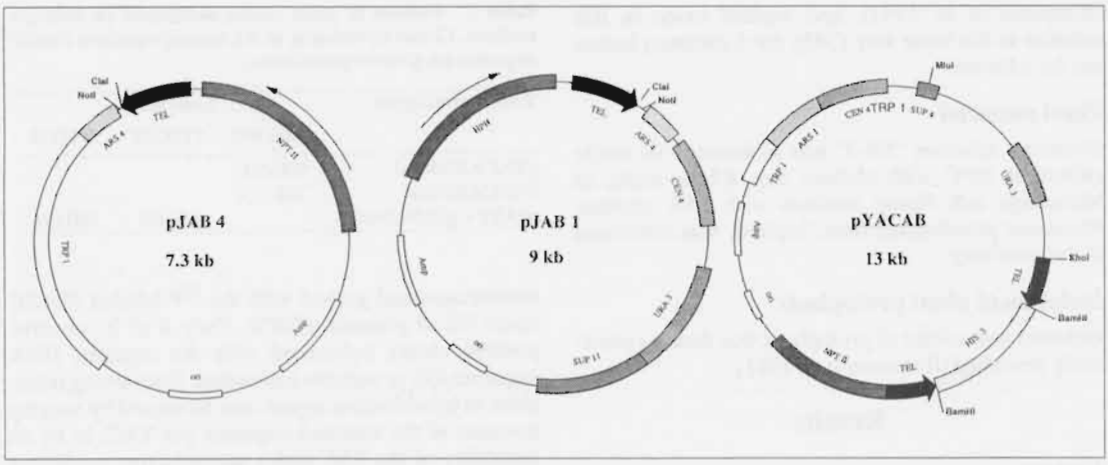

Fig. 1. Vectors used for construction of plant genomic libraries in yeast artificial chromosomes (YACs). Biological functions are abbreviated: Amp = Ampicillin resistance (*E. coli*); ori = origin of replication (*E. coli*); URA, HIS, TRP = auxotrophic selectable markers (yeast); CEN,ARS = centromere/replication (yeast); SUP = suppressor (colour marker for cloning) (yeast); TEL = telomere (yeast); HPH = hygromycin resistance (plants); NPTII = kanamycin resistance (plants).

(T. Hohn, pers. comm.). The NPTII gene was then excised as a 1.7 kb *Bam*HI fragment, and ligated into the unique *Bam*HI site of polylinker 2 of the vector pJS98 (Shero et al. 1991), to create pJAB4 (NPTII gene transcribed towards the TEL sequence).

Library construction

Ligation of high molecular weight DNA into YAC vectors. High molecular weight DNA of *L. esculentum* cv. 83M was isolated as described by van Daelen et al. (1989). Agarose plugs containing about 4 µg of total tomato DNA were digested overnight with the rare cutting restriction enzymes *Mlu*I or *Not*I (van Daelen et al. 1989).

Forty micrograms of the vectors pYACAB1 or pYACAB2 were digested to completion with the enzymes *Bam*HI and *Mlu*I. Samples were phenol/chloroform treated, ethanol precipitated, and dissolved in water. The vector arms were phosphatased (using calf intestine phosphatase as described by supplier), and ligated overnight with *Mlu*I digested genomic DNA. Agarose was removed by an agarase treatment, and ligation mix was stored at –20°C (100 µL/ligation reaction).

Vectors pJAB1 and pJAB4 were mixed in a ratio 1:1, and 40 µg of this mix digested to completion with the restriction enzymes *Cla*I and *Not*I. Phosphatase treatment of vector arms and ligation with *Not*I digested tomato DNA, was as described above.

Transformation of yeast spheroplasts. Spheroplast preparation and PEG induced transformation with the tomato DNA, cloned into YAC vectors, was as previously described (Guthrie and Fink 1991). Yeast strain AB1380 was transformed with *Mlu*I digested tomato DNA cloned into pYACAB1 or pYACAB2, and the yeast strains YPH252 (Mat ; ura3-52; lys2-801/amber; ade2-101/ochre; trp- 1; his3- 200; leu2 1) and YPH274 were transformed with *Not*I digested tomato DNAcloned into the vector combination pJAB1 and pJAB4. Transformed yeast spheroplasts were plated on selective medium lacking uracil. Individual colonies were transferred to microtitre plates containing selective medium, using toothpicks. Two replicas of the microtitre plates were stored at –70°C as glycerol stocks, and colonies of the original microtitre plates were dot-blotted onto Genescreen+ membranes.

Screening of the YAC libraries for the presence of the tomato specific HindIII repeat G2. Filters were prehybridised at 65°C overnight in 10% dextran sulphate, 1M NaCl, 1% SDS, 1 mg/10 mL salmon sperm DNA. Overnight hybridization with ^{32}P-labeled probe was in the same solution at 65°C, and there were two washes of 30 minutes at 65°C in 0.5X SSC, 1.5% SDS.

Inhibition of yeast with iodoacetamide

Yeast spheroplasts were prepared according to standard protocols (Guthrie and Fink 1991). After two washes by centrifugation (345*g*, 5 minutes), the spheroplasts were treated with 10mM iodoacetamide in lots of 10 mL at 5°C for 15 minutes with gentle agitation. After centrifugation (345*g* for 5 minutes) the spheroplasts were resuspended in 10 mL protoplast medium

(Bonnema et al. 1991), and washed twice in this solution in the same way (345*g* for 5 minutes) before use for a fusion.

Plant material

Nicotiana tabacum 'SR-1' was maintained in sterile culture at 25°C with 16-hour day, 8-hour night, in Murashige and Skoog medium with 20% sucrose. *Nicotiana plumbaginifolium*, haploid, was cultivated in the same way.

Isolation of plant protoplasts

Isolation and culture of protoplasts was done as previously described (Bonnema et al. 1991)

Results

Vectors

Several new YAC vectors suitable for plant transformation were produced (Fig. 1). We are currently testing the use of these vectors in complementation experiments (see below) using either YAC or total naked DNA isolated from the appropriate yeast strains, or by attempting to fuse yeast spheroplasts and isolated plant protoplasts.

Tomato gene library

Yeast transformation efficiencies of about 3×10^4 colonies/µg transforming DNA were obtained. Table 1 lists the number of clones obtained (only a small part of the ligation mixes was used). To estimate the average insert size of the YACs in both libraries, 30 random clones of the *Not*I bank in YPH252, and 30 random clones of the *Mlu*I bank in AB1380, were selected. Chromosomal DNA was isolated from 1 mL cultures (YPD) as described by van Daelen et al. (1989), chromosomes were separated on a pulsed-field electrophoresis gel, transferred to Genescreen+ membranes, and hybridised with pBR322. PBR322 sequences hybridize to the YAC vector arms. The average size of the YACs in the *Not*I bank was 250 kb; average size of YACs in the *Mlu*I bank was around 100 kb. Dot-blot filters were screened with the ^{32}P-labeled *Hind*III insert G2 of plasmid pTHG2 (tomato *Hind*III repetitive sequence G2, cloned into *Hind*III site of pBR322), and 38 of 2700 colonies (1.5%) showed stronger hybridisation than background hybridisation (Table 1). The percentage of colonies, hybridising with G2 (1.5%) is within the expected range of 0.5%–4.5%, assuming that the 450bp repeat occurs in 10000–75000 copies per haploid genome.

Yeast chromosomal DNA of clones, putatively containing the *Hind*III repeat squence G2, was isolated from 1 mL cultures (YPD). Chromosomes were separated by FIGE, transferred to Genescreen+ membranes, and probed with the ^{32}P-labeled *Hind*III insert G2 of plasmid pTHG2. Only 6 of 21 putative positive clones hybridised with the repeated DNA sequence G2, at variable intensities. The varying intensities in hybridisation signals can be caused by varying amounts of the repeated sequence per YAC, or by an instability of the YAC under non-selective conditions (chromosomal DNA was isolated from cultures grown under non-selective conditions).

Table 1. Number of yeast clones maintained on selective medium. Clones hybridising to the tomato repetitive *Hind*III sequence are given in parentheses.

YAC vector/digest	Yeast strain		
	AB1380	YPH252	YPH274
pYACAB2/MluI	900 (21)		
PYACAB1/JluI	700 (13)		
pJAB1 + pJAB4/NotI		800 (4)	300 (0)

We are currently further characterising the initial positive yeast clones. Using Southern hybridisation, PCR, and selective growth media, we will verify whether YACs, containing *Hind*III repetitive sequences can be maintained stably in yeast.

Fusion of yeast spheroplasts with plant protoplasts

In order to develop a successful fusion technique, it is first necessary to develop ways to inhibit division of yeast spheroplasts in plant tissue (protoplast) culture, otherwise yeast overgrows the plant cells within 2–3 days of the fusion experiment. A combination of two techniques was used to accomplish this.

Iodocetamide, a growth inhibitor, was used to kill the yeast cultures prior to fusion. 5mM iodoacetamide was sufficient to kill 90% of the yeast spheroplasts (Fig. 2). We noted that the quality of the yeast spheroplast preparation was important for an effective treatment; too much cell-degrading enzyme, or a too long digestion time, led to agglutination of spheroplasts. We found that addition of 5 mg/mL amphotericin to the plant culture medium did not affect protoplast regeneration, but inhibited the growth of yeast. In combination with the iodoacetamide pretreatment, addition of 5 mg/mL amphotericin after protoplast–spheroplast fusion, was sufficient to inhibit further yeast growth.

Initial fusion experiments have been conducted using either PEG-mediated or electroporation-mediated protoplast–spheroplast fusion and we are currently trying to select transgenic calli with kanamycin.

Discussion

The success of this kind of approach in mammalian cell systems indicates that perseverance with the plant

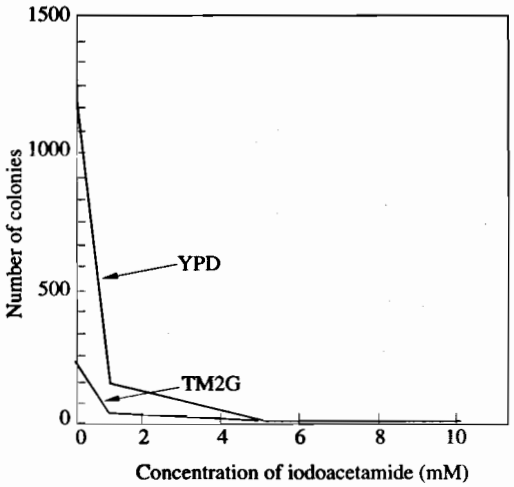

Fig. 2. The inhibition of yeast growth by iodoacetamide. YPD = yeast medium; TM2G = plant culture medium.

systems will also lead to success, since mammalian and plant cells have similar genetic complexities. Integration of YACs is likely to occur in plants, as it does in animal cells, rather than replicative maintenance, since yeast centromeres are very different to those of plant or mammals. Recombination of incoming transforming DNA, such as plasmid DNA with selectable markers, has been studied fairly extensively in somatic cells of these two systems, which show many similarities. The kanamycin resistance selection for transformed plants has already been tested in different kinds of plants.

We have developed a way of eliminating all of the yeast cells following the fusion treatment, an important achievement for further continuation of the project. Iodoacetamide used before fusion as described does not affect DNA transfer and has no effect on the regeneration of plant protoplasts. Amphotericin treatment is necessary after fusion to kill the few remaining yeast cells. Although we do not yet have transformed plants, we have found that following these treatments, protoplasts could be regenerated into plants. This is an important observation, since components of fungal cells are known to provoke defensive responses in plants that can lead to plant cell death.

A long-term objective of the lab is to clone tomato genes encoding resistance to the pathogen *Pseudomonas solanacearum* on a YAC, and to perform functional assays of the resistance genes in vivo. Once molecular markers closely linked to a resistance gene have been identified, a complete YAC library from a tomato line carrying the resistance genes will be screened for YAC clones containing these markers. YAC libraries will be screened using Southern hybridisation and crude lysate PCR (Kwiatkowski et al. 1990). These YACs will be used as starting points for chromosome walking towards the resistance genes. Extremities of the inserts of genomic DNA in YACs will be used for chromosomal walking. We propose to test YACs of interest by using the techniques of spheroplast–protoplast fusion that we are developing here. While the approach is of general importance, it is currently difficult to assess the chances of success using tomato variety Hawaii7996, since the genetic basis for resistance of this line is not yet known; we depend upon the identification of a major effect in order to try out the system.

Acknowledgments

We would like to thank Peter Hieter, Majiek Pietrzak, Jurek Paszkowsky and Thomas Hohn for valuable gifts of plasmid DNAs.

Breeding for Resistance to Bacterial Wilt in Tomato, Eggplant and Pepper

K.V. Peter, T.R. Gopalakrishnan, S. Rajan and P.G. Sadhan Kumar*

Abstract

A total of 165 tomato lines was evaluated for bacterial wilt resistance under field conditions. Line CL32-d-0-1-19 GS was resistant. This was confirmed in trials at other locations and under laboratory conditions where it was resistant to three different isolates. In 1984–85, an additional line, Louisiana Pink, was found to be resistant. Of the four methods of selection, single seed descent was most efficient in raising the level of resistance in selected lines. Resistant lines contained more tomatine. Line CL32-d-0-1-19 GS was released as Sakthi. For eggplant, 34 breeding lines and four other species of *Solanum* were evaluated. Annamalai, SM 6, SM 48, SM 58, SM 71, SM 72 and SM 74 were resistant. Of the four selection methods, single seed descent was most effective in raising the level of resistance. The genetic groups SM 6-1, SM 6-4 and SM 6-9 were immune in all the four cycles of selection. Lines SM 121, SM 126, SM 133, SM 135 and SM 140 were resistant in further evaluation trials. The resistant line SM 6-7 was released as Surya. The four chilli varieties, Pant C-1, KAU cluster, White Kandari and Chuna, were screened against nine isolates. KAU cluster was resistant to five isolates and was released as Manjeri.

PSEUDOMONAS solanacearum E.F. Smith causes wilt, and limits cultivation of tomato, eggplant and pepper in warm humid tropics. Breeding for disease resistance has been a major avenue for control of the disease.

The occurrence of races and biovars of *P. solanacearum* with different host reactions has made breeding for resistance a very challenging proposition. Although most breeding strategies to control wilt have not involved using mixtures of resistances in the field, Pande (1976) reported that mixtures of bengal gram with resistant components showed a reduction in wilt. Parlevliet (1979) extended the multiline concept to variety or line mixtures where the component genotypes differ for the race-specific resistance genes.

This paper reports on breeding trials with tomato, eggplant and pepper in the context of selection, inheritance and multiline use. The trials led to the release of varieties Sakthi in tomato, Surya in eggplant and Manjeri in hot pepper, which are now cultivated in wilt-prone soils of India.

Materials and Methods

Tomato

Evaluation of five lines for resistance to nine isolates. Five tomato lines—LE 79, Pusa Ruby, Rutgers, Venus and Saturn—were evaluated in vitro against nine virulent isolates of *P. solanacearum*.

Evaluation of 15 lines. Fifteen lines reported to be resistant were field-screened in infested soil for two seasons.

Enhancement of fruit size and wilt resistance. Attempts were made to enhance fruit size along with resistance of LE-79 (small fruited-type with green shoulders). Four methods of selection—mass, pure lines, single seed descent from elite selections (SSDES) and bulk—were tested.

Inheritance of resistance. To study the mode of inheritance, line CL32-d-0-1-19 GS was crossed with Pusa Ruby (a susceptible variety). The parents, F_1s, F_2s, BC_1s and BC_2s were grown in a wilt-infested soil.

Control by using mixtures. Attempts to control bacterial wilt by planting multiple sources of resistance were made. Six tomato lines possessing different gene

systems were used to develop 15 one-way F_1 hybrids and 15 50:50 physical mixtures. The physical mixtures were developed by alternate planting in the main field. The six parental lines, 15 one-way F_1 hybrids and 15 50:50 physical mixtures were grown in three replications. Parental lines, F_1 hybrids and mixtures were grown separately in each block. There were two rows of 10 plants for each entry and replication. Spacing was 70 × 60 cm. Pusa Ruby, the variety known to be susceptible,was spot planted to confirm presence of virulent inoculum in each and every planting spot. Plants were observed for incidence of bacterial wilt.

Crossing of two resistant sources. Two sources of reported resistance to bacterial wilt were incorporated in F_1 hybrids and the inheritance of resistance studied. The first source was a North Carolina type of resistance, expressed by 10 derivatives of Louisiana Pink; the second was derived from *Lycopersicon pimpinellifolium* (PI 127805 A). F_1 hybrids were developed through hand emasculation and pollination using *L. pimpinellifolium* as the male line and the 10 Carolina lines as female. The F_1s thus obtained were selfed to generate F_2s. The parental lines, F_1 and F_2s were grown in a diseased field and data were collected on numbers of plants wilted. Bacterial wilt in each of the segregating and nonsegregating generations was confirmed by ooze test.

Eggplant

The highly-segregating eggplant line SM 6 reported to be resistant to wilt (Anon. 1980) was evaluated against seven virulent isolates. Plants were raised and grouped into distinct classes based on fruit colour, fruit shape and absence or presence of prickles, keeping resistance intact. The 36 genotypes, which consisted of 11 classes in SM 6, two classes in SM 71 and five resistant genotypes from earlier trials were progressed through pure line selection and single plant selection.

Four selection methods—mass, single plant, pure line and single seed descent—were employed continuously for four cycles to improve the level of resistance.

Eleven genetic groups or types based on fruit colour, shape and presence or absence of prickles within the eggplant line SM 6 formed the basic material for selection and evaluation of bacterial wilt resistance under field conditions. Each of the 11 genetic groups was improved through four methods of selection through four successive cycles.

Heterosis breeding was conducted to upgrade three selected lines. The F_1s involved using these lines are SM 6-6 × Arka Kusumkar, SM 6-6 × SM 132, SM 6-2 × Pusa Purple Cluster, SM 6-2 × Plant Samrat, SM 6-7 × Arka Navneet and SM 6-7 × Plant Rituraj. The nine parental lines and six F_1 hybrids were further evaluated for resistance to bacterial wilt.

Hot pepper

Six hot pepper lines, four from India and two from the U.S.A. were evaluated for resistance to nine isolates. The four lines from India were *C. annuum* cvs. Pant C-1 and KAU cluster, and *C. frutescens* cvs. White Khandari and Chuna. The lines from the USA were Cubanelle and Early Calo-Wonder. Tetrazolium medium (Kelman 1954) was used to select virulent isolates. Disease indices were determined as symptoms appeared and scored as resistant (<25%), moderately resistant (25–50%) or susceptible (>50%). The experiment was repeated six times with 20 plants per reatment.

Two cultivars, KAU cluster and Pant C-1, and 10 F_1 hybrids of pepper were further evaluated in a highly wilt-sick soil for reaction to bacterial wilt. Inoculum potential of each planting spot was verified by wilting of known susceptible plant (Hungarian Wax). Ooze tests were done to confirm bacterial wilt.

Results and Discussion

Tomato

Evaluation of five lines for resistance to nine isolates. LE 79 was resistant to isolates K 60, 126408-1 and Tifton 80-1, while Venus was resistant to only 126408-1 (Rajan and Peter 1984). Pusa Ruby, Rutgers and Venus were susceptible to all the isolates.

Evaluation of 15 lines. The lines LE 124, LE 217, LE 79, LE 79LFG, LE 79DG,and LE 79SPF were resistant (Table 1).

Enhancement of fruit size and wilt resistance. Of the four methods of selection, SSDES was superior in breeding for enhancing levels of resistance to bacterial wilt: level of resistance was increased from 77.9 to 90.1%. When using SSDES, one or two of the largest seeds from each fruit borne on the most elite plant were taken and bulked. The selected progenies were advanced for three generations and raised in three different seasons in wilt-infested plots. The lowest susceptibility to bacterial wilt (9.8%) was recorded under SSDES in the third generation (Table 2).

Inheritance of resistance. For the inheritance of bacterial wilt resistance, a monogenic and incompletely-dominant gene action was recorded (Table 3).

Control by using mixtures. The lines LE 214 and LE 217 were resistant, with wilt reactions of 12 and 13%, respectively (Table 4). All F_1 hybrids except IIHR Bwr 93 × IIHR Bwr 34A and IIHR Bwr 34A × LE 206 were resistant. Among physical mixtures, six mixtures LE 214 + LE 217, LE 214 + IIHR Bwr 93, LE 214 + IIHR Bwr 34A, LE 217 + IIHR Bwr 93, LE 217 + IIHR Bwr 34A and IIHR Bwr 93 + IIHR Bwr 34A were resistant with disease reactions of 17%, 18%, 10%, 15% and 13%, respectively. The above mixtures had higher

1 × 2	8.69 (R)	1 + 5	40.00 (MS)
1 × 3	5.17 (R)	1 + 6	50.00 (MS)
1 × 4	10.35 (R)	2 + 3	16.67 (R)
1 × 5	5.17 (R)	2 + 4	18.33 (R)
1 × 6	17.24 (R)	2 + 5	10.00 (R)
2 × 3	6.90 (R)	2 + 6	25.00 (MR)
2 × 4	15.00 (R)	3 + 4	15.00 (R)
2 × 5	5.00 (R)	3 + 5	15.00 (R)
2 × 6	13.33 (R)	3 + 6	28.33 (MR)
3 × 4	6.90 (R)	4 + 5	13.33 (R)
3 × 5	8.33 (R)	4 + 6	30.00 (MR)
3 × 6	6.67 (R)	5 + 6	25.00 (MR)

[a] R = Resistant (20% plants wilted)
MR = Moderately resistant, 20–40% wilted
MS = Moderately susceptible, 40–60% wilted, and
S = Susceptible, 60% plants wilted.

levels of resistance than the expected values based on parental performance. The physical mixture with highest resistance, LE 214 + IIHR Bwr 93 (600.4 g/plant), had 24 fruits/plant, took 67 days to fruit set and 95 days to fruit harvest. The mixture IIHR Bwr 93 + IIHR Bwr 34A showed only 13% susceptibility, while the respective F_1 hybrid showed 35% susceptibility. IIHR Bwr A + LE 206 also showed an increased resistance to bacterial wilt when compared with its respective F_1 hybrid.

These observations confirm the utility of physical mixtures to check the spread of disease through the mechanism of obstruction as in a multiline. Shorter and Frey (1979) listed the advantages of mixtures over monocultures as: 1. more stable resistance to diseases; 2. greater stability of performance across diverse environments; and 3. higher yield through more efficient use of environmental resources.

Crossing of two resistant sources. A complementary type of gene action involving two separate gene systems determined resistance (Table 5). The gene system operating in *L. esculentum* was notated as $r_2\ r_2$ and that of *L. pimpinellifolium* as $r_1\ r_1$.

Eggplant

The disease reaction varied from immunity to moderate susceptibility in progenies developed through pure line selection. SM 6-7 was moderately resistant (Table 6).

Goth et al. (1983) inoculated seedlings of SM 6 with seven virulent isolates of *P. solanacearum* belonging to race 1 and race 3. SM 6 was resistant to TFP 13 (race 1), 126408-1 (race 1) and W 82 (race 3). It was tolerant to isolate A 21, but susceptible to isolates K 60 (race 1), TFP 12 (race 1) and Tifton 80-1 (race 1).

Of the four selection methods, SSDES was the most effective, raising the level of resistance to 92.8% during the fourth cycle of selection (Table 7) (Asha Sankar et al. 1987).

Among the 11 lines, SM 6-2, SM 6-6 and SM-6-7 were promising (Table 8), but were comparatively late to bear and had poor performance.

Among parental lines, the lowest wilt was observed in SM 132. SM 6-2, SM 6-6, SM 6-7 and Pusa Purple Cluster were also resistant to bacterial wilt. Among hybrids, the lowest percentage of wilt incidence was observed in SM 6-6 × SM 132 (5.26%). SM 6-2 × Pusa Purple Cluster was also resistant to bacterial wilt (Table 9).

R = Resistant; MR = Moderately resistant; S = Susceptible; HS = Highly susceptible; and NT = Not tested.

Hot pepper

No pepper lines tested were resistant to all nine isolates and only isolate A 21 was pathogenic to all the pepper lines (Table 10). The most resistant line was Pant C-1, a line derived as an advanced generation selection from a cross between NP46-A and Khandari. It was susceptible to only Florida isolates A 21, TFP 12, TFP 13 and 126408-1. KAU cluster was resistant to five isolates, and White Khandari had differential resistance (Peter et al. 1984).

Screening of Eggplant Accessions for Resistance to Bacterial Wilt

Hanudin* **and M.A. Hanafiah Gaos†**

Abstract

Bacterial wilt caused by *Pseudomonas solanacearum* is one of important diseases affecting Solanaceae and is capable of reducing production of solanaceous crops by up to 100%. Forty-four eggplant accessions from the collection of the Plant Breeding Division of Lembang Horticultural Research Institute (LEHRI) were evaluated in Subang for resistance against bacterial wilt race 1 biovar 3 in a randomised block design with two replications. Before screening for *P. solanacearum* resistance, a disease nursery was established. Only the accession LV-209 (Gelatik Hijau) from Ciparay-Bandung was resistant, whereas other accessions tested gave susceptible to moderately resistant reactions.

BACTERIAL wilt caused by *Pseudomonas solanacearum* E.F. Smith is an important disease of eggplant (*Solanum melongena* L.) worldwide. The bacteria can survive in soils in areas of mild to warm climates (Kelman 1953), and can be a limiting factor for growing eggplant. In North Carolina, yield losses of 50% have been observed by midsummer (Winstead and Kelman 1952); losses between 75 and 81% have been recorded in India (Rao 1976); and 50–100% losses were observed in the wet and dry seasons in Indonesia (Hanudin and Gaos, unpublished data).

Vegetable crops resistant to bacterial wilt have been studied in some countries, especially tomatoes, but there is little published work on eggplant. Eggplant accessions Kopek Ungu Kecil Cairo, Ping Tung Long Red Taiwan, and Hijau Kecil Jakarta were resistant to bacterial wilt in Indonesia, based on two field experiments conducted in Segunung and Sukamandi (Hanudin and Gaos, unpublished data).

The purpose of the study reported here was to screen eggplant accessions obtained from Lambang Horticultural Research Institute (LEHRI) for resistance to *P. solanacearum* race 1 biovar 3 in Subang, a lowland area in West Java.

*Segunung Horticultural Research Station, Segunung.
†Lembang Horticultural Research Station, Lembang, Indonesia.

Materials and Methods

The trial was conducted at the Subang Experimental Garden (110 m above sea level) from January–June 1991. A randomised block design with two replications was used. The treatments included resistance and susceptibility checks on 44 accessions of eggplant (Table 1).

Before screening could be conducted, a disease nursery was established. After the land had been prepared, 21-day-old seedlings (DOS) of susceptible eggplant accession LV-877 were planted in beds. The distance between the rows was 20 cm. All the tops of the leaves of 35 DOS were cut with scissors which had been dipped in a suspension of *P. solanacearum* race 1 biovar 3 (1×10^9 cfu/mL). The land was rototilled 20 days after inoculation when about 90% of the plants had wilted.

The test accessions were seeded and after 21 days seedlings were transplanted to the disease nursery. All accessions were planted next to the susceptible check (LV-877) and a resistant check (LV-209) at a distance of 20 × 30 cm. Rice-straw mulch was placed on the beds to preserve soil humidity.

Observations on bacterial wilt were made every week. For rating and classifying resistance, the following scale was used: 80–100% survival = resistant (Rs); 60–79% survival = moderately resistant (MR), 30–59% survival = moderately susceptible (MS), and 0–29% survival = susceptible (Ss).

[d] Mean values followed by the same letter are not significantly different according to Scott-Knott Test at 5% level.

Results and Discussion

Variance analysis of the percentage of wilted eggplant accessions was highly significant. Under the test conditions, only the accession LV-209 showed a high level of resistance against bacterial wilt race 1 biovar 3. Five accessions—LV-266, LV-349, LV-740, LV-2806, and LV-2810—were moderately resistant, whereas all other accessions were moderately susceptible or susceptible (Table 1).

In North Carolina, eggplant Kopek from Java and Matale from Sri Lanka were resistant to *P. solanacearum* (Winstead and Kelman 1952). While the genetics of resistance in eggplant have not been intensely studied, it has been reported that expression of resistance under high temperatures may be lacking, as was reported by Krausz and Thurston (1975) for tomato. In the experiments reported here, air temperatures ranged from 23.5–33.4°C and it is possible that some of the accessions reported resistant elsewhere were not resistant at these high temperatures.

Differences in resistance may also be due to the occurrence of different races or pathotypes. Buddenhagen and Kelman (1964) reported that three races can occur. In addition to the differences in races that may cause some pathogenic variation from location to location, the breakdown of resistance may also be due to a synergistic effect of parasitic nematodes. In these trials we found a number of different genera of nematodes, including *Criconemoides*, *Helicotylenchus*, *Meloidogyne*, *Rotylenchus*, and *Xiphinema* (Hanudin, unpublished data).

Inoculation Procedures and the Evaluation of Peppers for Resistance to *Pseudomonas solanacearum*

K.D.A. Perera, G.L. Hartman and J.M. Poulos*

Abstract

Experiments were conducted to develop an effective inoculation procedure to evaluate host plant resistance in peppers to *Pseudomonas solanacearum*, the causal agent of bacterial wilt. Three inoculation techniques—tooth-pick stabbing, soil drenching with root severing and soil drenching without root severing—were tested with two strains of *P. solanacearum* on 20- and 35-day-old seedlings. Tooth-pick stabbing and soil drenching with root severing yielded similar percentages of wilt in susceptible and resistant lines, indicating that they were equally effective screening procedures. The root-severing technique, however, was relatively easy to apply and more clearly resembled natural inoculation than did tooth-pick stabbing. The final percentage wilt was not significantly affected by the age at which the plants were inoculated but the rate of wilting was higher for younger seedlings. Although there was no significant difference in the percentage wilt caused by the two strains, the pepper strain PS71 was slightly more aggressive than the tomato strain PS4. Of 81 varieties screened for resistance, several showed complete absence of wilting with the root-severing technique.

BACTERIAL wilt caused by *Pseudomonas solanacearum* is one of the most important and widespread bacterial disease of crops in tropical environments. The pathogen has a wide host range representing 44 families (He et al. 1983). Recent investigations have shown that it attacks several woody perennials, including cashew (*Anacardium occidentale*) (Shiomi et al. 1989), custard apple (*Annona* spp.) (Mayers and Hutton 1987) and Alexandra palm (*Archontophoenix alexandrae*) (Akiew and Hams 1990). Among the solanaceous crops, potato, tobacco and tomato are greatly affected by the disease, while under certain tropical conditions pepper, especially sweet pepper, is also severely affected. There is little information, however, about the extent of damage caused to pepper by bacterial wilt.

Resistant varieties offer an effective means of controlling bacterial wilt. There has been some success with resistant varieties of tomato, tobacco and peanut. In potato, resistance genes from wild species have been introduced into cultivated species (Schmiediche 1986). The resistance, however, was found to be temperature sensitive and strain specific (French and De Lindo 1982). Opeña et al. (1990) concluded that both additive and non-additive gene action regulate the genetic system for wilt resistance in tomato. Tung et al. (1990) found that wide genetic background and good adaptation were the key factors that favoured resistance to bacterial wilt in potato.

The importance of effective screening methods for the evaluation of germplasm for resistance to bacterial wilt has been emphasised. Winstead and Kelman (1952) found that puncturing the stem and adding a drop of bacterial suspension, or pouring a suspension over wounded roots, were equally effective for causing disease on susceptible tomato, tobacco and peanut plants. They concluded that injury to roots was the best technique to differentiate between resistant and susceptible plants. In tomato and many other hosts, young plants were more susceptible than older plants. Mew and Ho (1976) concluded that resistance to *P. solanacearum* in tomato was not necessarily comparable between seedlings and adult plants. Segregating populations were best screened under field conditions at the flowering stage. Field epidemics of bacterial wilt of pepper have been difficult to create (Yoon et al. 1988). Development of a standardised technique for the evaluation of pepper germplasm is therefore necessary. A series of experiments was conducted to determine the

*Asian Vegetable Research and Development Center, Shanhua, Tainan, Taiwan, 741.

most effective inoculation procedure that can be applied to screen large germplasm collections under screenhouse conditions.

Materials and Methods

Comparisons of inoculation methods

Two strains of *Pseudomonas solanacearum* were tested using three inoculation techniques on susceptible sweet pepper plants of the commercial cultivar Giant Bell (F_1) (Evergrow Seed Co.) that were 20- and 35-days old. A split-plot design with four replications was used, with main plots as two strains and subplots as a factorial of different ways to inoculate plants and different plant ages. Seedlings were raised in 9-cm-diameter pots and inoculated individually with bacterial strains PS4 and PS71. The inoculation techniques were: (1) tooth-pick stabbing; (2) soil drenching with root severing; and (3) soil drenching without root severing. For tooth-pick stabbing, sterile tooth-picks were rubbed in bacterial colonies and inserted into the stem at the axil of the second or third expanded leaf below the stem apex. Soil drenching with root severing was made after injuring the roots by passing a knife into the soil 1.5 cm away from the seedling stems and pouring a bacterial suspension over the severed roots. Soil drenching without root severing was done by pouring a bacterial suspension over the soil surface. For soil drenching, 10^7 cell/mL bacterial suspension was used at a rate of 30 mL per seedling. Plants in the control treatments for each method were treated with water. Diseased plants were counted daily for the first 2 weeks after inoculation and at 2-day intervals thereafter. Plants with all the leaves wilted were counted as wilted.

Evaluation of host resistance

Five plants of twelve resistant and four susceptible lines were inoculated with strain PS71 25 days after emergence. After inoculation, plants were kept in a heated glasshouse (24–34°C). Two inoculation procedures—tooth-pick stabbing and soil drenching with root severing—were conducted as two experiments using a randomised complete block design with three replications each. For soil drenching, seeds were sown in soil in 50 × 34 cm plastic flats. Six lines were planted in three rows in each flat. The space between rows was 10 cm with 5 cm between plants. At the time of inoculation, plants were 19–29 cm high and had 7–10 expanded leaves. The soil surface between the lines was cut with a sharp knife and 1.2 L of bacterial suspension (10^7 cell/mL) was added to each flat. Diseased plants were recorded at 2-day intervals for the first week after inoculation and at 5-day intervals thereafter up to 28 days after inoculation (DAI). For tooth-pick stabbing, plants were raised in 9-cm-diameter pots and inoculated as previously described. At the time of inoculation, plants were 11–15 cm high and had 7–9 expanded leaves. Data on percentage wilt were recorded at 28 DAI.

Seventy-six accessions of pepper tested from entries in the International Hot Pepper Trial network (INTHOPE) were inoculated in another two experiments, one having 35 accessions, the other 41 accessions, using soil drenching with root severing. The inoculation procedure was as described previously. The experiment with 35 accessions was first conducted from 26 November 1991–30 January 1992 (winter), with the plants kept in a heated glasshouse after inoculation. The same experiment was repeated from 4 June 1992–31 August 1992 (summer); the other 41 accessions were tested in the 1992 summer.

Results

Comparisons of inoculation methods

Wilt symptoms were first observed 3 DAI on plants inoculated with infested tooth-picks. Plants that were inoculated by soil drenching with root severing and soil drenching without root severing wilted 8 and 12 DAI, respectively. Plants that were inoculated with infested tooth-picks developed wilt rapidly in young plants, with over 75% of plants wilted 15 DAI (Fig. 1a). At 39 DAI, however, there was no significant difference in percentage wilt due to tooth-pick stabbing (85%) and soil drenching with root severing (77%). In older plants, disease progress was rapid in soil drenching with the root-severing method by 14 DAI and by 39 DAI 85% of the plants had wilted (Fig. 1b). There was no significant difference in final percentage wilt due to soil drenching with root severing (85%) vs tooth-pick stabbing (73%). Soil drenching without root severing caused 40% of young seedlings to wilt and 28% of older seedlings. The overall wilt percentage by soil drenching alone was significantly less than that of tooth-pick stabbing and soil drenching with root severing (Table 1).

The two strains, PS71 and PS4, did not cause any significant difference in the final disease rating. Pepper strain PS71 was more aggressive, causing 77% wilt, 22% more than that of the tomato strain PS4 at 39 DAI (Fig. 2).

Evaluation of host resistance

Most of the susceptible varieties had over 90% wilt within 10 DAI with both methods of inoculation. Disease development was rapid when plants were inoculated by infested tooth-picks and symptoms occurred within 15 DAI for all sensitive cultivars tested. Using the root-severing technique, maximum

wilt occurred at more than 25 DAI. Comparisons of the area under the disease progress curve (AUDPC) calculated for the root-severing technique indicated a significant difference among the varieties (Table 2). Tooth-pick stabbing caused from 0–100% wilt with significant differences among varieties. The most susceptible varieties had 90–100% wilt with both inoculation methods. The high AUDPC values obtained from the root-severing method were related to highly susceptible cultivars as determined by final wilt. Some varieties that had the same final percentage wilt differed in AUDPC values. There were differences in the rate at which these varieties succumbed to wilt, some wilting more rapidly than others. The varieties that had 0–5% wilt from root-severing had 0–30% wilt using the tooth-pick method. The varieties that had 50–65% wilt using the root-severing technique, had 25–83% wilt with the tooth-pick method. Among the varieties tested, the plants which survived using the tooth-pick method showed some lesion development above or below the wound point along the stem. In some instances, the top of the plant died but later recovered by axillary bud growth. These were scored as resistant plants. MC 4 and CA 8, two varieties that had no wilt with either method of inoculation showed localised stem necrosis at the pricking point.

The 76 accessions of pepper screened using the soil drenching with root-severing technique showed different degrees of resistance and susceptibility among the cultivars (Tables 3 and 4). Some of the accessions showing high and moderate levels of susceptibility during the winter displayed a high level of resistance in summer (Table 4). Factors such as soil moisture variability and mite infestation during the summer screening may have interfered with host–pathogen compatibility.

Discussion

Tooth-pick stabbing and soil drenching with root severing were equally effective procedures to evaluate bacterial wilt resistance in peppers. The tooth-pick method showed rapid development of disease symptoms, as the direct introduction of the pathogen into the vascular tissues enabled faster movement and multiplication of the pathogen. Most of the plants inoculated with the tooth-pick method showed slight leaf chlorosis and stem distortion above the point of insertion of the tooth-pick, often retarding the terminal bud growth. One disadvantage of the method was the extra care necessary to avoid damage to the seedling when the tooth-pick was inserted into the stem, especially in younger plants. The root-severing method allowed for a more passive introduction of the bacteria into the plants. Similar final wilt incidence resulting from tooth-pick stabbing and root-severing techniques indicated that root severing of the secondary roots provided an ample opportunity for bacterial infection. Under field conditions, with transplanting or when inter-cultivation practices are carried out using farm implements, pepper plants are often subjected to root-severing. As natural infection occurs mainly through these wounded roots, the soil drenching with root severing technique may mimic the field situation. When large numbers of accessions are evaluated, this is an easier and less labour-intensive technique. In addition, for further selection for other traits, soil drenching with root severing has an advantage because plant growth is not distorted, as sometimes occurs with the tooth-pick stabbing method. These advantages indicate that the root-severing methodology may be

more suitable for evaluation of bacterial wilt resistance in pepper.

Young pepper plants succumbed to wilt more rapidly than older plants. This phenomenon has been observed in tomato and many other crops, and it has been suggested that resistance in young plants cannot be compared to that found in older plants (Mew and Ho 1976). Nevertheless in the tests reported here, the final level of susceptibility in the pepper accessions did not change significantly due to the age at which the plants were inoculated.

The 81 accessions of peppers screened using the soil drenching and tooth-pick method showed different degrees of resistance and susceptibility among cultivars. Some of the accessions showed complete absence of wilting, indicating that a high level of resistance was available among the germplasm tested. In the repeated experiment, the resistance level was consistent for most of the cultivars, with some exceptions. Observed differences in resistance levels in the same cultivars tested in two seasons may be due to genotypic differences within the cultivar or physiological imbalances resulting from mite infestation or soil moisture variability. In these experiments, accessions MC 4, CA 8, CAB, LV 2323 (Jatilaba), and Cipanas were the best sources of resistance to bacterial wilt of pepper.

Current U.S. Breeding Efforts for Improving Bacterial Wilt Resistance in Flue-Cured Tobacco

V.A. Sisson* and E. A. Wernsman†

Abstract

Through pedigree selection over the past 50 years tobacco breeders have been successful in increasing the level of resistance to bacterial wilt (*Pseudomonas solanacearum*) in flue-cured varieties. Despite this success, bacterial wilt continues to cause significant economic losses to tobacco each year. Current breeding efforts seek to: 1. increase the level of wilt resistance; 2. improve the yield and quality characteristics for highly resistant varieties; 3. locate and utilise new sources of resistance to bacterial wilt; and 4. develop new breeding and evaluation methods for bacterial wilt resistance. In an effort to improve the levels of wilt resistance available in the breeding program, crosses have been made with TI 448A, the original source of resistance, and Xanthi, TI 79A, 79X, DSPA, and Enshu. These efforts have achieved only moderate success. High levels of resistance have been recovered but additional backcrossing is needed to recover flue-cured characteristics. Haploid breeding methods are being used as a means of obtaining simultaneous disease resistance evaluation and line stabilisation. A simple *in vitro* procedure that permits rapid cloning of haploid plants has been developed recently. Utilisation of this breeding technology leads to improved rates of genetic gain and shortens the time for cultivar development.

BACTERIAL wilt (*Pseudomonas solanacearum* E.F. Smith), commonly referred to in the United States as Granville wilt, is a major disease of flue-cured tobacco (*Nicotiana tabacum* L.). This disease has been reported in all of the flue-cured tobacco producing areas in the U.S. Initially, it was found in the Middle Belt area located in the rolling hills of the piedmont region of North Carolina. It has since spread into the sandy coastal plain areas, where it is the most important chronic disease problem in the Eastern and Border production belts. Even tobacco growers in the adjacent states of South Carolina and Virginia are now plagued by serious bacterial wilt infestations.

Over the last 10 years disease loss estimates for bacterial wilt on tobacco in North Carolina have averaged 1.4% of the crop, compared with an average total disease loss of 6.9%. Normally, bacterial wilt losses rank a close second behind those from black shank, caused by *Phytophthora parasitica* var. *nicotianae* (Breda de Haan) Tucker. These two diseases account for nearly 50% of all flue-cured tobacco disease losses. In many areas bacterial wilt is the most important disease problem.

Wilt symptoms on tobacco are not unlike those of many other crops. Unilateral wilting of the leaves is characteristic. Initially only one or two leaves wilt, with only half of the leaf wilting. Affected leaves become light-green to yellow. Tan or brown discoloration develops in the vascular tissue just beneath the bark. Infected roots become blackened and decay. Eventually all of the leaves wilt and die, but remain attached to the stalk.

Control measures such as crop rotation, early stalk and root destruction, and soil treatment with nematicides or multipurpose fumigants have been effective in reducing losses caused by this disease, but no one measure has provided adequate control. Corn, soybean, small grains, fescue, and lespedeza have been found to be acceptable rotation crops. Most U.S. flue-cured tobacco farmers follow a 2-year rotation, which can provide a significant disease reduction; however, longer rotations are recommended, especially if disease infestations are high. Multipurpose fumigants are available, but have shown limited effectiveness when used as the only means of control. While all of these

cultural practices are important in the control of bacterial wilt, the use of resistant varieties is still the principal means of control for wilt in tobacco.

Breeding for Bacterial-Wilt Resistance in Tobacco: Historical Perspective

The early history of breeding for resistance to bacterial wilt in tobacco in the U.S. spans most of the first half of the 20th century. It is a classic plant-breeding success story. Kelman (1953) provides a thorough review for the interested reader. While bacterial wilt was present in the U.S. before 1900, the first report of serious outbreaks of this disease on tobacco came in 1903 (Stephens 1904) in Granville County, North Carolina. A search for resistant varieties was initiated the very next year. This search proved futile, however, and a report in 1917 (Garner et al. 1917) indicated that none of the available tobacco varieties or *Nicotiana* species possessed resistance high enough to warrant further testing. During this time and continuing through the mid-1940s, the economic impact of the disease was devastating, and many tobacco farmers were forced to abandon their farms. In the early 1930s the U.S. Department of Agriculture (USDA) sponsored several plant collection trips to Mexico and Central and South America to acquire new tobacco germplasm. Greenhouse screening trials were begun in 1934 to test more than 1000 new germplasm accessions for bacterial wilt resistance. Most lines were quickly eliminated. One collection, Tobacco Introduction (TI) 448A from a field in Colombia, South America, however, exhibited good resistance and was identified as a potential source of resistance for use in breeding. In 1938, TI 448A was tested in field trials. The results were very encouraging because this line not only exhibited high resistance, but also possessed flue-cured characteristics. Crosses were made to a high quality flue-cured variety. In 1945, Oxford 26 was released as the first flue-cured tobacco variety with high resistance to bacterial wilt. This variety became the source of resistance for all wilt resistant varieties to follow.

Since the development of the first bacterial-wilt-resistant variety nearly 50 years ago, tobacco breeders have continued to make gradual improvements in the overall level of resistance utilising this single source of resistance. A traditional backcross breeding approach was used in the initial transfer of resistance. Pedigree selection has since become the most widely used breeding method for cultivar development. Today, tobacco farmers can access more than a dozen flue-cured varieties with high resistance to bacterial wilt and relatively good yield and quality traits (Table 1).

Resistant varieties have helped control bacterial wilt for many years, making tobacco production possible on bacterial-wilt-infested soil. However, varieties carrying resistance to bacterial wilt do not possess complete resistance. Even those varieties classified as highly resistant are subject to infection, especially

under conditions where soil infestation levels are high and ameliorating cultural practices are not carefully followed.

Despite the fact that bacterial wilt is widespread throughout the flue-cured tobacco production area, less than 13% of the acreage in 1991 was planted to varieties with high resistance. Farmers have been reluctant to grow these varieties. Less resistant varieties are typically grown because of their higher yield and better agronomic and quality features. U.S. flue-cured tobacco farmers are still looking for a highly-resistant variety with superior agronomic performance.

Current Breeding Efforts

The USDA's Crops Research Laboratory (formerly the Tobacco Research Laboratory) has a long and rich heritage in breeding for bacterial-wilt resistance. Located in Granville county, North Carolina, site of the first severe disease problems, pathologists and breeders at this laboratory were directly involved in the development of the first wilt-resistant variety. This focus on bacterial-wilt resistance has continued through the years and today remains a major part of a cooperative USDA-State breeding program.

Our objectives with regard to breeding for bacterial-wilt resistance have changed over the years. Most new cultivars now possess some resistance to bacterial wilt. Current breeding efforts have the following objectives: (1) to improve the yield and quality characteristics of highly-resistant varieties; (2) to increase the level of resistance in flue-cured varieties; (3) to locate and utilise new sources of resistance; and (4) to develop new and more efficient breeding and evaluation methods. In the remainder of this paper, current research and development addressing each of these objectives will be discussed.

Breeding for improved yield and quality

Significant improvements in the yield and quality of flue-cured tobacco have occurred over the years. Bowman et. al (1984) used a regression technique to compare the performance of all new cultivars entered into the North Carolina Official Variety Test over the period 1954–1981. He estimated the average annual yield increase for new cultivars was 49.5 kg/ha (approximately 2% per year), of which 68% was attributed to improved technology and 32% (or 16 kg/ha) to genetic improvement. Genetic gains in leaf quality were also evident, but of a lower magnitude. This study did not differentiate among cultivars with different combinations or levels of disease resistance, but did show a definite favorable trend among all cultivars. Since many cultivars with improved wilt resistance were released during this time, it can be assumed that the yield and quality of these cultivars also improved.

Current efforts to improve yield and quality still follow traditional breeding approaches. This is necessitated, to some extent, by the rigid quality standards established for each of the various classes and types of tobacco (i.e., flue-cured, air-cured, cigar, oriental, etc.). The amount of unique germplasm any one class can tolerate without adversely affecting leaf quality is quite limited. Therefore, where new cultivars are the principal objective, their source populations are usually restricted to segregating generations from single- or three-way crosses among released cultivars of a common class. While this practice restricts the germplasm pool, good cultivars have been developed. The flue-cured tobacco cultivar NC 729 (Sisson 1992), which has some of the highest bacterial-wilt resistance among currently available cultivars, was recently released from our laboratory. It produces above average yield, and ranks among the best varieties for quality. Several other new cultivars with similar performance have also been developed recently by commercial breeders.

Increased resistance to bacterial wilt

As already noted, even those cultivars classified as highly resistant are subject to infection in heavily infested soils. Efforts to enhance current levels of resistance are under way. These efforts are limited, in part, by the fact that current resistance in flue-cured tobacco is derived from a single source, TI 448A. Resistance from this source has been reported to be recessive and controlled by multiple genes (Smith and Clayton 1948). Effective use had been made of pedigree selection to improve resistance. Segregating populations are normally planted in a *P. solanacearum*-infested disease nursery. Seeds from disease-free F_2 plants are saved and planted as F_3 progeny rows in a wilt nursery the following year. Visual selection for resistance is practiced among lines, and plants within lines. The best F_3 plants are self-pollinated and tested the next year. Each succeeding generation is traceable to a single-plant selection in the previous generation. Bulking or combining of seed from multiple plants is generally done after the F_5 generation, at which time plants are considered genetically stable. This pedigree selection process has been successful in accumulating resistance genes and improving bacterial-wilt resistance over the years. Although the increments of increase are typically small, continued progress has been made in improving the level of wilt resistance. This method permits simultaneous selection for resistance to other diseases as well.

At this point we would like to briefly mention the procedures used for detecting resistance to *P. solanacearum*. Our evaluation of tobacco for

bacterial-wilt resistance is based mainly on test plantings of large populations in naturally-infested fields. Because the disease is so wide spread in the flue-cured tobacco production area, fields with naturally high levels of inoculum are relatively easy to locate, and often farmers are willing to allow the use of such land since it has little value for tobacco production. We have found it necessary, however, to alternate yearly plantings between test plots and a highly susceptible variety to prevent reductions in the natural inoculum levels in the soil over time. In our bacterial wilt nursery at the Oxford Tobacco Research Station, we have also found it beneficial to artificially inoculate the field each year (Moore et al. 1963). This not only helps to maintain a stable inoculum level over time, but more importantly provides for a uniform development of wilt in successive years. Several litres of inoculum are prepared just before the transplant operation for addition to the transplant water at the time of transplanting. The root zone of each transplant receives approximately 100 mL of water containing between 1×10^6 to 1×10^8 cells/mL. For many years a strain of *P. solanacearum* designated K60 was used as the inoculum source. We have recently switched to a more virulent strain designated H20. While this procedure has been successful in inducing satisfactory levels of disease development, seasonal conditions still have a significant impact on overall wilt severity. Disease counts are taken every 3–4 weeks depending on disease development and a disease index is calculated from disease counts taken over the entire season.

Various greenhouse inoculation procedures (Winstead and Kelman 1952) have been used in evaluating resistance of tobacco to bacterial wilt; however, most breeders have experienced difficulty in utilising these tests. In most instances, these procedures are limited by the number of plants that can be tested, the labour involved, and the greater variation in results from test to test. In addition, disease severity, even in the most resistant lines or varieties, exceeds that observed under natural conditions in the field. Furthermore, field plantings allow evaluation of characteristics other than resistance. We are not using greenhouse evaluations at this time.

Locating and utilising new sources of wilt resistance

The development of improved wilt resistance in tobacco has obviously been hampered by the absence of sources of resistance. Resistance from TI 448A has been used exclusively in U.S. cultivars. Other possible sources of resistance have been identified, but to date have proven too difficult to work with or simply have not been used. Low resistance was reported in the old U.S. flue-cured cultivars Davis Special, Pinkney Arthur, and 400 (Clayton and Smith 1942). These cultivars show evidence of resistance under mild wilt infestation, but under severe conditions appear as completely susceptible. They have no value for crossing with susceptible genotypes, as the resistance proves inadequate and impossible to recover in full (Clayton and Smith 1942).

Several lines or strains have been described as having mild or moderate resistance. These include: TI 79A and Sumatra C from Indonesia; Xanthi, a cultivar grown in Turkey; and the Japanese domestic cultivars, Awa, Hatano, Kokubu, and Odaruma. Early work (Clayton and Smith 1942) with the non-Japanese lines showed that progenies from crosses between these lines and flue-cured varieties typically have small leaves and are generally poor plants. It was at this same time that work with TI 448A was showing promise and these lines were abandoned as functional sources of wilt resistance.

Other than TI 448A, very few lines have been reported to have high bacterial-wilt resistance. The breeding line designated 79X is a stable line developed from a cross between TI 79A and Xanthi (Clayton and Smith 1942). Interestingly, crossing these two moderately resistant lines resulted in strains with higher resistance than either of the parental lines. When 79X was used as a source of resistance in the development of flue-cured cultivars, the resistant segregants tended to have small leaves and poor quality (Clayton and Smith 1942). Japanese workers have reported (Matsuda and Ohashi 1973) that the domestic cultivars Enshu and Hatanodaruma have high wilt resistance, but in our disease nurseries in the U.S. we have not observed the same high level of resistance which they report for these cultivars. Nevertheless, they do appear to possess resistance.

Thus, while we have relied on a single source of bacterial-wilt resistance in breeding U.S. flue-cured tobacco cultivars, there are a number of other possibilities. Breeding work and genetic studies have provided valuable information on the inheritance of wilt resistance in tobacco (summarised in Table 2). Results suggest there are different genetic systems ranging

Table 2. Mode of inheritance of bacterial wilt resistance from different sources.

Source	Inheritance	Reference
TI 448A	Recessive, polygenic	Smith and Clayton 1948
79X	Recessive, polygenic	Smith and Clayton 1948
Awa	*Rps*	Matsuda and Ohashi 1973
Enshu	*Rps*, polygenic	Matsuda and Ohashi 1973
DSPA	polygenic	Matsuda 1977
Sumatra C	*Rps*, polygenic	Matsuda 1977
Xanthi	*Rxa*	Matsuda 1977

from single dominant genes to recessive polygenes controlling wilt resistance. Accumulating and combining the genetic factors from these different resistant sources may therefore make it possible to enhance the level of resistance.

In 1980, a long-term research project with this goal was initiated by Dr G. R. Gwynn, tobacco breeder at the Crops Research Laboratory at that time. Although he retired in 1988, this important work has been continued. The following is a brief review of its development and current status.

The general breeding scheme selected is one of phenotypic recurrent selection and backcrossing. To yield initial single-cross populations, the resistance sources, TI 448A, DSPA, TI 79A, 79X, Xanthi, and Enshu, were crossed using a partial diallel mating design which included the flue-cured variety Speight G-15. These F_1 hybrids were naturally self-pollinated. The next year, F_2 populations were grown in a bacterial wilt nursery. Disease-free plants of single-cross populations were intermated. These double-cross hybrids were naturally self-pollinated in the greenhouse during the winter. During the third year, the double-cross populations were grown in a bacterial wilt disease nursery. Disease-free plants were allowed to naturally self-pollinate. In year 4, the $F_{2:3}$ lines were again grown in a disease nursery and one or more of the following procedures was performed on selected lines: (1) plant-to-plant crosses were made for a third generation of intermating; (2) superior F_3 lines from second generation intermating were advanced by self-pollination; and (3) superior F_3 lines from second generation intermating were backcrossed to a high quality flue-cured cultivar. Since 1985 there has been continued evaluation, selection and advancement within the various generations of intermating and backcross populations. In addition, a second backcross to a good yielding, high quality flue-cured variety has been made.

After working with these non-flue-cured and somewhat exotic sources of resistance, it is understandable why they were abandoned by early workers. Progress has been difficult and slow. Although it has been possible to identify and maintain high levels of resistance among the breeding lines selected, resistance appears to be no greater than that currently available in some existant highly resistant flue-cured cultivars. In addition, plant type of most resistant selections is uniformly poor, even after two backcrosses to high quality flue-cured parents. While the progress has been somewhat disappointing, it also likely reflects the complexity of this effort and reaffirms the need for additional wilt-resistant germplasm for tobacco.

As mentioned previously, disease evaluations are carried out exclusively in field nurseries. Environmental conditions have a major impact on bacterial development and disease expression. It is likely we will need to utilise more discriminating methods of disease evaluation before we can fully take advantage of these additional sources of wilt resistance.

Development and application of new breeding methods

The last area we wish to discuss is a new breeding strategy for developing wilt-resistant germplasm, which takes advantage of some unique features of the tobacco plant. Recent research has demonstrated the feasibility and efficacy of the use of haploids in tobacco breeding. Haploids are sporophytic plants which have the gametophytic chromosome number of the species. For tobacco, which is an allotetraploid, n = 2x=24. Plant breeders have long recognised the potential of haploids as tools for the simplification and acceleration of breeding programs. Although they have been observed in most plant species, only a few species can produce sufficient numbers of haploids for practical breeding purposes. Because of the relative ease with which haploids can be produced and the large haploid populations that can be generated, tobacco has been used as a model system for haploid research. Tobacco haploids can be produced by in vitro anther culture (anther-derived haploids) or by interspecific hybridisation using tobacco as the female and pollen of the wild species *N. africana* Merxm. and Butler (ovule-derived haploids). Completely homozygous diploid (or doubled haploid, DH) lines are produced by doubling the chromosome complement of haploid individuals. Chromosome doubling is accomplished by either treating small anther-derived haploid plantlets with an aqueous colchicine solution (Burk et al. 1972), or haploid plants may be chromosome-doubled by in vitro tissue culture of the leaf midvein (Kasperbaur and Collins 1972). Research has shown (reviewed by Wernsman 1991) that tobacco doubled haploids of maternal origin are competitive with conventionally inbred genotypes, while anther-derived doubled haploids typically have reduced performance.

Tobacco breeding in the haploid state

Many of the procedures for producing and using haploids in tobacco breeding are now well established (Fig. 1). In the initial steps F_1 plants from desired single-crosses are pollinated with the pollen from *N. africana*. Capsules form normally and produce large quantities of seed. When germinated, those seeds which are true interspecific hybrids (99+%) will die in the cotyledonary stage due to a seedling lethality factor associated with *N. africana*. The survivors are either aneuploids which contain one or more *N. africana* chromosomes, or maternal- or ovule-derived haploids.

These plantlets can usually be distinguished by various morphological differences.

Haploid seedlings are transplanted to pots and moved to the greenhouse. Once these plants have attained sufficient size, leaf mid-veins are aseptically cultured on a shoot-forming medium to restore the diploid chromosome compliment. Sections of a leaf midvein are surface sterilised, first in 70% ethanol, followed by 10% sodium hypochlorite; rinsed in sterile distilled water; and placed on a shoot-forming tissue culture medium (Kasperbaur and Collins 1972). Small shoots form in 3–4 weeks and are excised and transferred to a rooting medium. Shoots normally root in 10–20 days. Rooted plantlets are potted in soil and allowed to produce seed. Completely homozygous lines are thus recovered in about 3 years from the time of the initial cross. This can be contrasted to the 5–6 years required to reach genetic stability by conventional methods.

A number of procedures has been developed to enhance the efficacy of this breeding strategy. Single detached leaves of haploid plants can be inoculated with TMV, PVY, and wildfire (Rufty et al. 1987). Disease reactions can be observed on the detached leaf. This procedure makes it possible to test for multiple disease resistance in a non-destructive evaluation of the haploid plant. In this way, only those haploids expressing desired combinations of resistance would be doubled for further testing and evaluation.

Because the procedure using *N. africana* produces haploids in the form of seed, production of haploid plants can be synchronised with the growing season. Seeds can be sown in plantbeds in the spring where haploids are then identified. These haploids are transplanted directly to a disease nursery for testing. Resistant selections must be rescued for doubling the chromosome number before the haploid plant succumbs to the disease. Problems with endophytic fungi and bacteria in field-grown plants are a major obstacle, and make leaf mid-vein culture from field grown plants difficult.

A more recent procedure involves vegetatively cloning haploid plants. One clone is retained in a secure environment as a future explant source for doubling, and remaining clones can be subjected to destructive testing.

Haploids are produced in the normal manner from crosses with *N. africana* and grown to the 5-leaf stage. The apical meristem and surrounding leaves are cut from the plant, surface sterilised, and aseptically cultured in small glass vials containing a tissue-rooting medium. Roots typically form in 10–12 days at 26°C.

At the time of decapitation all but two leaves are removed. In 10 days, leaf axillary buds produce shoots or suckers. When these shoots reach 2.5–3.5 cm, they

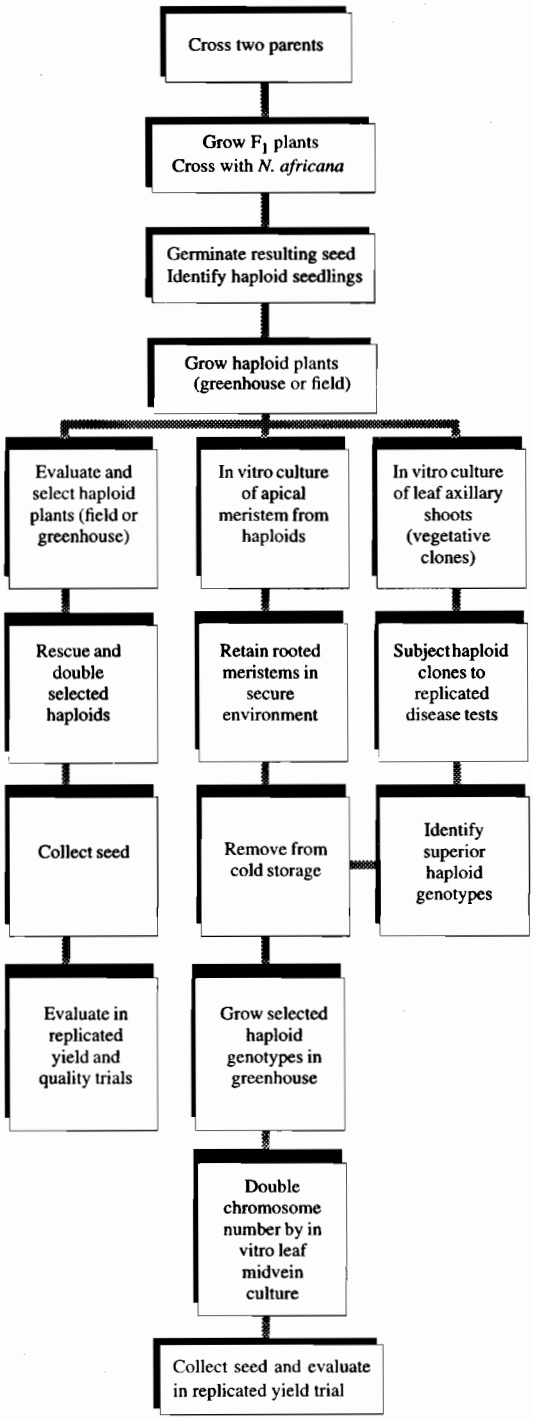

Fig. 1. General scheme for tobacco disease breeding in haploid plant populations. Alternative methods allow direct screening of haploid plants or screening of haploid clones.

are cut from the plant, surface sterilised, and cultured on a rooting medium similar to the apical meristem. Rooting again occurs in 10–12 days. Since tobacco contains multiple axillary buds per leaf, secondary shoots will develop in leaf axils and can be rooted as well.

This procedure permits a number of clones or copies (up to six or eight) of each haploid plant to be produced. These multiple copies permit replicated test of individual genotypes, thereby increasing the precision of testing.

Clones can be stored safely for up to 90 days in a low temperature incubator maintained at 4°C/18-hour photoperiod. Plant growth is greatly retarded in this environment. As clones are needed for testing they are removed from low temperature storage and transferred to a normal 26°C incubator for 24 hours, the medium washed from the roots, and the clone transplanted to soil. In three weeks time the plant will attain sufficient size to be transplanted to the field or greenhouse. Upon completion of the disease-screening test, healthy explants for chromosome doubling of selected genotypes can be obtained from individuals maintained in the secured environment.

Haploid breeding combined with vegetative cloning provides an extremely powerful procedure for screening for bacterial wilt. It allows the use of field nurseries which we feel is a key to evaluating bacterial wilt resistance. Selected genotypes are instantly true breeding. These true breeding lines can be subjected to replicated yield and quality trials and are ready for immediate release to the growers if found superior.

This approach has been used successfully in the screening and development of black shank resistant breeding lines. We have also successfully tested haploid plants in the field for bacterial wilt resistance, but this is the first year we have actually begun to use the vegetative cloning aspects of this procedure in developing wilt resistant cultivars. Based on our experience with black shank resistance, however, we are confident that this approach will be successful in improving the efficiency of our breeding effort for bacterial-wilt resistance and result in the development of new and improved wilt-resistant flue-cured tobacco cultivars.

Screening Eucalyptus Selections for Resistance to Bacterial Wilt Caused by *Pseudomonas solanacearum*

J.C. Dianese and M.C.G. Dristig*

Abstract

Methods of screening *Eucalyptus* spp. for resistance to *Pseudomonas solanacearum* were tested by using differences in inoculum concentrations, inoculum placement on the host, physiological ages of seedlings, and bacterial isolates. Screening for tolerance to bacterial wilt among 42 genotypes belonging to 20 *Eucalyptus* spp. was conducted in a growth chamber at 28 to 30°C with a 12-hour photoperiod. Seedlings with 8–10 leaves were inoculated with isolate UnB 577 of *P. solanacearum* by placing a 10 µL drop of 10^6 cfu per mL in the axil of the second pair of true leaves previously wounded with a needle. The plants were rated for disease 10 and 18 days later. Tolerance was present in one selection of each of the following species: *Eucalyptus camaldulensis, E. citriodora, E. cloeziana, E. deanei, E. pellita, E. resinifera,* and *E. tereticornis*. Two selections each of *E. grandis* and *E. torelliana* were also wilt tolerant.

PREVIOUS screenings for resistance to bacterial wilt in *Eucalyptus* spp. were conducted in Brazil by Cruz and Dianese (1986) and Dianese et al. (1990) with *Pseudomonas solanacearum* biovar 1 (Dianese and Takatsu 1985). In China, Wu and Liang (1988) selected genotypes tolerant to biovar 3 isolates. Selections tolerant to biovar 1 were detected in *E. deglupta, E. pellita* and *E. tereticornis* in Brazil (Dianese et. al. 1990), while tolerance to biovar 3 was reported from China in *E. saligna, E. citriodora* and *E. exerta* (Wu and Liang 1988). The objective of this study was to develop techniques for mass screening of *Eucalyptus* genotypes for resistance to bacterial wilt.

Materials and Methods

Experiments were conducted in growth chambers using 10 replications of one plant each. The virulence of nine isolates of *P. solanacearum* was tested by inoculating 6- to 8-leaf seedlings of a susceptible selection of *E. grandis* in wounds in the axil of the second pair of true leaves. A virulent isolate (UnB 577) and a weakly-virulent isolate (UnB-573) were then selected for the experiments conducted to develop the method of inoculation.

*Departamento de Fitopatologia, Universidade de Brasília, 70910-900 Brasília, DF, Brazil.

Seedlings were transplanted to 200 mL plastic cups at the 2–6-leaf stage. When at the 10–12-leaf stage, plants were inoculated separately with isolates UnB 577 and UnB 573 using five different methods: (i) soil treated with a 10 µL suspension of 10^6 cfu; (ii) same as treatment 1, but roots wounded using a small scalpel; (iii) leaf axil wounding with a needle before placing a 10 µL suspension; (iv) laying 10 mL of suspension around the crown of the seedling just after transplanting to cups; and (v) root wounding and dipping in 10^6 cfu suspension before transplanting.

The most favourable physiological age for inoculation was tested by comparing seedlings with 2–4, 6–8, and 10–12 true leaves. Inoculated plants were incubated for 18 days in growth chambers at 30°C and a 12-hour photoperiod. Data from the above experiments were used to select the inoculation procedure to screen for resistant genotypes and also to test the virulence of isolates on a selection of *E. grandis* from Passagem, State of Minas Gerais, Brazil.

Disease scores were recorded at 10 and 18 days after inoculation using the following disease scale: 1= plants without symptoms; 2 = wilted plants; and 3 = dead plants (Fig. 1). The following wilt index (WI) was calculated for each genotype:

$$WI = [(1 \times f_1) + (2 \times f_2) + (3 \times f_3)] / (f_1 + f_2 + f_3);$$

where 1, 2, and 3 are the disease rating scores and f_1, f_2, and f_3 are the respective frequencies of each type.

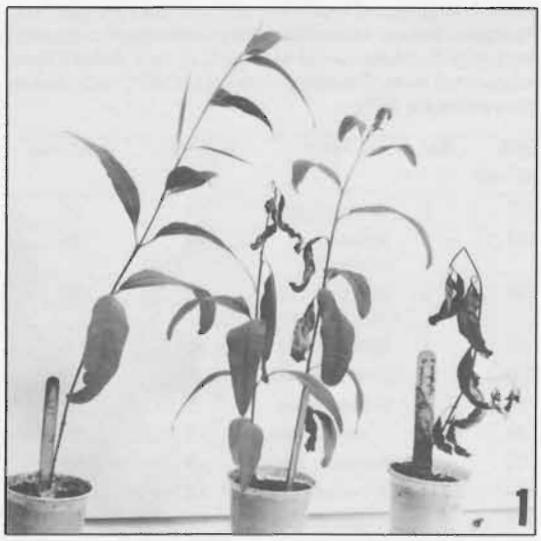

Fig. 1. Disease rating scale used to evaluate bacterial wilt resistance in *Eucalyptus* spp. 1 = healthy (plant on left), 2 = wilted (centre plant), and 3 = dead (plant on right).

Forty-two genotypes belonging to 19 *Eucalyptus* species were sown in autoclaved seedbeds containing limed red-latosol soil fertilized with NPK (4-14-8). Healthy seedlings with 2–6 true leaves were transplanted to 200 mL plastic cups containing the same substrate and allowed to grow until 10–12-leaf stage.

Results and Discussion

In preliminary tests, the three inoculum concentrations (10^4, 10^6, and 10^8 cfu per mL) were efficient in causing wilt and in separating isolate UnB 577 from a weakly virulent isolate (UnB 573). The concentration of 10^6 cfu per mL was chosen for screening genotypes.

Of the five methods of inoculation, four induced satisfactory levels of wilt but the application of a 10 µL drop to wounded leaf-axils was the most practical way for mass screening. Ratings taken 10 and 18 days after inoculation (DAI) were consistent. Except for the application of inoculum suspension around the crown of recently transplanted seedlings, the other four methods allowed for distinction between the virulence of the two isolates on *Eucalyptus* spp. (Table 1).

Seedlings with 10–12 leaves were differentially affected by the virulent and weakly-virulent isolate. The gradient of symptoms was consistent both with the virulence levels of the isolates and the time of exposure to the bacterium (Table 2). Plants with 10–12 true leaves were considered best for routine screening for resistance.

Table 1. Comparison of five methods of inoculating *Eucalyptus grandis* with *Pseudomonas solanacearum* (isolates UnB 577, highly virulent and UnB 573, weakly virulent). Disease ratings were taken 10 and 18 days after inoculation (DAI) with 10^6 cfu per mL.

Method of inoculation[a]	10 DAI		18 DAI	
	Wilt (%)	Death (%)	Wilt (%)	Death (%)
Isolate UnB 577				
A	40	10	40	40
B	10	40	40	40
C	20	60	20	70
D	10	20	60	20
E	20	50	40	60
Isolate UnB 573				
A	20	0	40	30
B	10	10	70	10
C	10	0	50	20
D	10	0	80	10
E	10	40	50	40

[a]A = 10 mL of bacterial suspension was applied to the soil after transplanting 10-12-leaf stage seedlings in 200 mL plastic cups; B = same as A but the roots were wounded with a scalpel; C = 10 µL drop of suspension applied to wounded axil of the second pair of true leaves; D = 10 mL of suspension applied to crowns of seedlings just after transplanting into cups; and E=roots of seedlings dipped in inoculum for 30 minutes before transplanting seedlings into the plastic cups.

Table 2. Effect of the physiological stage of seedlings of *Eucalyptus grandis* on bacterial wilt caused by two isolates of *Pseudomonas solanacearum*. Disease was estimated by the percentage of dead and wilted seedlings 10 and 18 days after inoculation (DAI) in growth chamber at 30°C and 12-hour photoperiod.

	10 DAI		18 DAI	
True leaves	Wilt (%)	Death (%)	Wilt (%)	Death (%)
Isolate UnB 577				
2–4	10	60	10	60
6–8	0	20	20	30
10–12	40	20	20	50
14–20	60	0	80	10
Isolate UnB 573				
2–4	0	50	0	60
6–8	20	0	30	0
10–12	30	0	30	0
14–20	0	0	10	0

The virulence of nine isolates on *E. grandis* varied, and only isolate UnB 577 wilted all plants. Isolate UnB 575 also was highly virulent (Table 3).

When the same *Eucalyptus* selection was inoculated with 10 isolates, isolate UnB 577 was less virulent

Table 3. Virulence rating of nine isolates of *Pseudomonas solanacearum* on a selection of *Eucalyptus grandis* from Passagem, State of Minas Gerais inoculated in growth chamber at 30°C and 12-hour photoperiod during 15 days.

Bacterial isolates	Original hosts of the isolates	Wilt (%)	Death (%)
539	*E.urophylla*	10	0
540	*E. grandis*	10	10
573	*E. urophylla*	20	0
574	*E. pellita*	20	30
575	*E. urophylla*	20	70
576	*E. pellita*	20	0
577	*E. urophylla*	40	60
579	*E. urophylla*	10	0
603	*E. urophylla*	10	0

to *E. grandis* than isolates UnB 588 (biovar 1), UnB 210 (biovar 2), and UnB 139 (biovar 3) from tomato; UnB 68 (biovar 2) from potato; UnB 75 (biovar 3) from *Solanum gilo;* and UnB 468 (biovar 3) from bell pepper (Table 4).

All the isolates tested were virulent to *E. grandis*, and only UnB 577 was used to screen for resistance. The bacterium infected and multiplied in the xylem of wilting and also non-wilting (tolerant) plants as previously observed (Dianese et al. 1990). This indicates that tolerance to bacterial wilt was present in 12 of the genotypes tested which were arbitrarily defined as those with a WI (wilt index) less than 1.5 at 10 DAI and a WI less than 1.8 at 18 DAI. The tolerant genotypes belonged to eight of 18 *Eucalyptus* spp. tested (Table 5). Figures 2 and 3 show, respectively, responses of susceptible and tolerant species.

Table 4. Response of a selection of *Eucalyptus grandis* from Passagem, State of Minas Gerais to growth-chamber inoculations with *P. solanacearum* biovars 1, 2, or 3 isolated from solanaceous hosts. Seedlings were kept at 30°C and 12-hour photoperiod for 18 days.

UnB isolates	Biovar	Hosts	Wilt (%)	Death (%)
577	1	*E. urophylla*	40	50
115	1	*Solanum tuberosum*	20	45
588	1	*Lycopersicon esculentum*	10	90

Management of Bacterial Wilt of Groundnut Using Genetic Resistance and Cultural Practices

V.K. Mehan, S.N. Nigam, and D. McDonald*

Abstract

The use of bacterial wilt-resistant groundnut cultivars is an effective and practical way of reducing yield losses from the disease. Many sources of resistance have been reported from the People's Republic of China, Indonesia, and Uganda where bacterial wilt is a serious problem. Much progress has been made in the development of several wilt-resistant cultivars in China and Indonesia. Several of these cultivars are now widely grown in various parts of Indonesia (e.g. Gajah, Pelanduk, Tupai) and south and central China (e.g. El Hua 5, Lu Hua 3, Yue You 92, Guiyou 28, Zhong Hua 2), and have had much impact in reducing yield losses in wilt-affected areas. The wilt-resistance in Indonesian cultivars Schwarz 21 and Gajah continues to be useful even after several decades of their cultivation. However, recent studies in China have highlighted the existence of strains/pathotypes in the wilt pathogen, *Pseudomonas solanacearum*. This necessitates more critical genetic evaluation of wilt-resistance to elucidate host-pathogen interactions. Future research into stability and durability of wilt-resistance, as well as incorporation of resistance to other yield reducing diseases, are indicated. Crop rotation with feasible non-host crops (e.g. rice and maize) is also a useful means of reducing the disease levels in humid tropical areas. An integrated approach to disease management, involving wilt-resistant cultivars, crop rotation, intercropping, and crop sanitation, is emphasised.

BACTERIAL wilt (BW) of groundnut (*Arachis hypogaea* L.) occurs in several countries of southern Asia, Southeast Asia, Africa, and North America, but it is economically important in only the People's Republic of China, Indonesia and Uganda (Hayward 1990; He 1990; Machmud 1986; Mehan et al. 1986; Simbwa-Bunnya 1972). The disease has recently been reported as severe in some groundnut-producing areas, of Vietnam (Mehan et al. 1991). In the People's Republic of China, the disease is most severe in central and southern groundnut-producing areas where more than 0.2 million hectares are infested with the wilt pathogen, *Pseudomonas solanacearum* E.F. Smith, and yield losses of 10–30% are common (Liao et al. 1990). However, within any region there are variations in disease incidence and severity attributable to soil type, pathogen populations, cropping patterns, climatic factors and groundnut cultivars. The persistence of the pathogen in soil, and its wide host range, often limit the effectiveness of cultural and chemical control practices. Although rotation with non-host crops provides effective disease management, control of BW of groundnut has been achieved mainly with resistant cultivars. In this review paper we provide information on sources of resistance to the disease and examine how these sources are being utilised in the breeding of resistant cultivars. Resistant cultivars and cultural control measures are considered for use in integrated disease management systems.

Host Plant Resistance

Sources of resistance

Attempts to select wilt-resistant groundnut cultivars were first made in Indonesia in the 1920s. Most of the cultivars selected as BW-resistant, such as Hybrid No. 3, Katjan Toeban, and Pure Line 21, later showed high mortality of plants under severe disease pressure (Palm 1926). Subsequently, from an extensive wilt resistance breeding program in Java, a highly resistant cultivar, Schwarz 21, was developed by selection from a wilt-resistant groundnut line of unknown origin (Schwarz and Hartley 1950). Resistance in this cultivar was

confirmed in several field and greenhouse screening tests (Jenkins et al. 1966; Machmud and Lasimin 1987; Machmud and Middleton 1988; Yeh 1990). From extensive screening of several hundred germplasm and breeding lines in wilt-sick plots in Indonesia, several lines with varying levels of resistance to BW were identified (Machmud and Middleton 1988, 1990; Sharma and Soekarno 1992).

Various lines/cultivars resistant to *P. solanacearum* have also been reported from Mauritius, South Africa, Uganda, the United States, the Philippines and Sri Lanka (Orian 1949; Sellschop 1947; Jenkins et al. 1966; Simbwa-Bunnya 1972; Natural et al. 1988; Jayasena and Rajapaksa 1990). However, some of these were susceptible in China (Sun et al. 1981).

Many sources of resistance have been reported from the People's Republic of China where a selection and breeding program for wilt resistance was begun in the late 1950s. Of over 500 germplasm lines screened in Guangdong Province in the early 1960s, 30 wilt-resistant lines were identified (Zhou and Liu 1962; OCRI 1976). From extensive screening of over 4000 germplasm accessions and breeding lines in the 1970s and 1980s, many additional sources of resistance were identified (OCRI 1977; Xu et al. 1980; Wang et al. 1983; Tan and Liao 1990; Duan and Li 1987; Duan et al. 1991). These included Xiekangqing, Taishan Sanlirou, Lukangking 1, Yue io 589, Huangchuan Zhili, Tianjing Dou, Taishan Zhengzhu, and many lines of 'Chinese Dragon' type. Some of these (Taishan Zhengzhu, Yue io 589) were later shown to be susceptible (Sun et al. 1981). In the next decade, several other cultivars (Xiekongchung, Sueitian, Teishan Sanliyue, and Huongzhuanzhili) were reported resistant (Sun et al. 1981).

Recently, several wilt-resistant cultivars with high yield and quality were released in China (Yeh 1990; Liao et al. 1990). These cultivars are Lu Hua 3, El Hua 5, Zhong Hua 2, Yue You 92, Yue You 256, Guiyou 28, and Jinyou 3121. The cultivars El Hua 5, Zhong Hua 2 and Yue You 92 have shown stable wilt resistance in multilocation tests carried out in Hubei Province, China (Liao et al. 1990). These wilt-resistant lines/cultivars have approximately 90% plant survival compared with below 10% survival in susceptible cultivars in infested fields.

Differential disease reactions of some lines/cultivars have been noted in different locations. For instance, the lines PI 414332 and NC Ac 17130, found resistant in China (Yeh 1990), were susceptible in Indonesia (Machmud and Middleton 1988, 1990). Some cultivars (Gajah, Kidang, Macan, Banteng) reported resistant in Indonesia were moderately resistant in China (Yeh 1990). Likely causes of variations in wilt reactions of these lines include inoculum pressure, pathogen virulence, environmental factors and genetic background of the lines. Many of the reported sources of resistance have only field resistance to BW: they show substantial wilt incidence in glasshouse screening tests. Only a few lines have been found resistant to BW in both field and glasshouse tests (Machmud and Middleton 1990).

Field screening under high disease pressure is useful for identifying sources of resistance. In most cases, glasshouse tests and disease ratings in the field do not correlate well. In general, certain inoculation techniques (e.g. hypodermic syringe inoculation) used in the glasshouse give high levels of wilt in most genotypes (Machmud and Middleton 1990). It is noteworthy that several accessions of Schwarz 21 (ICG 1609, ICG 5313, and ICG 8666) glasshouse tested in Bogor, Indonesia, showed susceptibility (over 60% wilt incidence) with this technique, while this cultivar has shown consistent resistance in many field and glasshouse tests. These genotypic variations in reactions to BW (in field and glasshouse tests) can be attributed to pathogen virulence, inoculum pressure, and inoculation techniques. Stem-inoculation techniques often give higher disease levels than root-inoculation techniques. It is important to employ inoculation techniques (in glasshouse screening tests) that simulate natural field conditions, especially in terms of infection route. Some studies have shown higher levels of wilt-resistance in selected progenies of Gajah and several other wilt-resistant lines than in unselected bulk of Gajah and other lines (Sharma and Soekarno 1992). This emphasises the need for maintaining a high level of resistance in cultivars by proper selection and maintenance of breeder seed through plant progeny evaluation, particularly under high disease pressure.

Lines/cultivars resistant to BW are listed in Table 1. A majority of resistance sources belong to *Arachis hypogaea* subsp. *fastigiata*. However, there are some sources, such as Tianjin Dou, that belong to subsp. *hypogaea*.

High levels of resistance to BW have also been reported in several wild *Arachis* species (Yeh 1990). These species are *A. duranensis*, *A. spegazzini*, *A. correntina*, *A. stenosperma*, *A. cardenasii*, *A. chacoense*, *A. villosa*, *A. appressipila*, *A. pusilla* and *A. glabrata*. These species also have high levels of resistance or immunity to rust, late leaf spot and early leaf spot pathogens. Some of the wilt-resistant lines/cultivars possess resistance to two or more major groundnut diseases. For instance, some Peruvian accessions (PI 393641, PI 393531, NC Ac 17127, NC Ac 17129) have resistance to rust and late leaf spot (Subrahmanyam et al. 1980; Mehan et al. 1986; Yeh 1990). Some interspecific hybrid derivatives such as CS 7 and CS 30 possess resistance to bacterial wilt and rust and late leaf spot

(Yeh 1990). Schwarz 21 has resistance to BW, verticillium wilt and pythium pod rot (Frank and Krikun 1969; Jenkins et al. 1966).

Breeding for resistance to bacterial wilt

Breeding for wilt-resistance was first initiated in Indonesia, where bacterial wilt was the most important groundnut disease. A highly resistant cultivar, Schwarz 21, was selected from a local population of groundnut in the early 1920s. This cultivar was derived from wilt-resistant populations obtained from the Cheribon region of Java, where the disease was especially severe. Schwarz 21 and its derivatives are grown predominantly in Java, and have made groundnut cultivation possible in areas where other cultivars previously suffered heavy yield losses. In the 1950s, crosses between Schwarz 21 and other introductions from Japan, Israel and the USA led to the development of several wilt-resistant cultivars, viz. Gajah, Kidang, Banteng, and Macan. These four wilt-resistant cultivars were released in Indonesia in 1952. Several other crosses between Gajah and Kidang and introductions from Honduras and the USA led to the development of wilt-resistant cultivars Rusa, Anoa, Pelanduk, Tupai and Tapir, and these were released in 1982–83 (Anon. 1983, 1984). Resistance in these cultivars has been verified in several field and greenhouse tests in Indonesia (Machmud 1986; Wakman 1988). Recently, hybridisation of the improved BW-resistant Indonesian cultivars with other accessions has been achieved, with particular emphasis on incorporation of resistance to rust and leaf spots. Emphasis on maintenance of wilt resistance has been a high priority objective throughout the history of crop improvement in Indonesia. Genetic resistance to bacterial wilt is essential, and selections are made in wilt-sick plots. It is noteworthy that resistance can be enhanced by selection under severe bacterial wilt pressure in wilt-sick plots (Sharma and Soekarno 1992).

In the People's Republic of China, breeding efforts in the 1960s led to the development of two moderately

resistant cultivars, Yue You 589 and Sueitien. Later an exotic source of wilt resistance was crossed with a local cultivar and several wilt-resistant cultivars, including Yue You 92 and Yue You 256, were developed. During the past 15 years, much attention was given to breeding groundnuts for resistance to BW in China. High yielding wilt-resistant cultivars have been released and have an important role in disease control and increased groundnut production in areas infested with BW. These include Jinyou Guiyou 28, Lu Hua 3, El Hua 5, and Zhong Hua 2 (GAAS 1987; Liao et al. 1990; Wang et al. 1990). Of these, Lu Hua 3 is the highest yielder in infested areas of southern China (He 1990).

Several wilt-resistant germplasm lines and cultivars have been used as resistant parents (Teishan Sanliyue, Teishan Zhenzhu, Xiekongchung, Tianjin Dou, Taishan Sanlirou, Xiekangqing and Schwarz 21) in several wilt-resistance breeding programs in China. Two wilt-resistant lines with good general combining ability, Xiekangqing and Taishan Sanlirou, have been used extensively as resistance donors in wilt-resistance breeding programs (Liao et al. 1990). In recent years, breeding emphasis has been placed on combining BW-resistance with resistances to rust and leaf spot diseases. In breeding for resistance to BW, some parents with rust and late leaf spot resistance have been used, and some breeding lines (Yue You 202, Yue You 266) with resistance to rust and BW have been developed (Liao et al. 1990).

Wilt-resistant groundnut cultivars released in Indonesia and China are given in Table 2. Most of these belong to the Spanish group.

Wilt-resistant cultivars have been developed in lower latitudes, where selection pressures are greatest. This demonstrates a need for extensive evaluation of germplasm in low-latitude areas for sources of bacterial wilt resistance. However, the primary origin of BW-resistant genotypes should be determined.

Genetics and mechanisms of resistance

Although the results from limited inheritance studies (Liao et al. 1986) involving Spanish groundnuts are suggestive of partial dominance of resistance and the involvement of three pairs of major genes and some minor genes, they are not conclusive. More detailed studies with different botanical types and strains or pathotypes in controlled environments are required to elucidate the nature of inheritance of BW resistance in groundnut.

Little is known about the mechanism(s) of resistance to BW. Resistance is probably manifested mainly through host defence to disease development, though there might be differences among cultivars in their ability to resist invasion by *P. solanacearum*.

Table 2. Bacterial wilt-resistant groundnut cultivars released in Indonesia and China.

Cultivar	Pedigree	Year of release
Schwarz 21	Selection from a wilt-resistant line from the Cheribon region of Java (Indonesia)	1925
Gajah	Schwarz 21 × Spanish 18-38	1952
Banteng	Schwarz 21 × Spanish 18-38	1952
Kidang	Schwarz 21 × Small Japan	1952

Some infected plants do not display wilting symptoms, and partial wilting symptoms can be observed in resistant genotypes (Liao et al. 1990). The expression of resistance may be influenced by the genetic background of the host plant, inoculum level, virulence of the pathogen and environmental factors.

Stability and durability of resistance

Although it has been suggested that the stability and durability of genetic resistance to BW may be questionable because of the possible genetic variability of the wilt pathogen (Lum 1990), this is not borne out by the continued resistance of cultivars such as Schwarz 21 and Gajah that are extensively grown in Indonesia. These cultivars were released to farmers in 1925 and 1952, respectively. It is noteworthy that in one of the wilt sick plots in the Hubei Province, China a resistant cultivar was successfully grown continuously for nine years without losing its resistance.

There is little information on the distribution and variability of the wilt pathogen in farmers' fields or on the genetic composition of local cultivars. Some studies e.g. Tan et al. 1991 have demonstrated the existence of highly virulent strains or pathotypes (Table 3) and, in the light of these findings, it is important to study stability of resistance through collaborative trials at different disease 'hot spots' and in areas where different strains or pathotypes are suspected. A set of

Table 3. Reactions of groundnut isolates of *Pseudomonas solanacearum* on some diagnostic groundnut cultivars[a].

Cultivars	Pathotypes of *P. solanacearum*[b]						
	1	2	3	4	5	6	7

Fuhuasheng	S	S	S	S	S	M	S
Ehua 1	S	S	S	S	S	M	S

[a]Data from Tan et al. (1991): R = Highly resistant (< 10% wilt incidence); M = Moderately resistant (10-50% wilt incidence); and S = Susceptible (> 50% wilt incidence)

[b]Thirty-six isolates from various parts of China were divided into seven pathotypes based on their virulence to six cultivars with different levels of BW-resistance.

differentials should be included in these trials. Some description of the strains of the pathogen to which these lines/cultivars are subjected is obviously important.

Durability of wilt-resistance should be ensured by adopting appropriate breeding strategies and by bringing in new resistance genes from diverse sources and wild species.

Impact of wilt-resistant cultivars

Releases of wilt-resistant cultivars in Indonesia have significantly reduced yield losses in various parts of the country where disease was a serious problem. Two early bred resistant cultivars, Schwarz 21 and Gajah, are widely grown in Java where the disease previously caused heavy yield losses (25–45%) in susceptible cultivars. Some wilt-resistant cultivars (Pelanduk, Tupai) developed in the 1980s are now becoming popular with farmers. The disease in farmers' fields is now sporadic because of the cultivation of improved Indonesian cultivars resistant to BW. Wilt-resistant, high-yielding cultivars play an important role in disease control and increased groundnut production in several provinces of China where BW is a production constraint. El Hua 5 is grown in most of the bacterial-wilt-affected areas, covering over 10000 ha, in central China (Liao et al. 1990). Zhong Hua 2, an early maturing wilt-resistant cultivar with wide adaptation, is becoming popular with farmers in southern China. Yue You 92, Lu Hua 3, Jinyou 3121 and Guiyou 28 are grown extensively in Guangdong, Guangxi, Fujian and Shandong provinces. Some recently developed cultivars have multiple resistances to BW and rust and are awaiting release in the near future. They are expected to further increase groundnut production in areas where both BW and foliar fungal diseases are serious.

Cultural Measures

Rotation of groundnuts with non-host crops such as rice, sugarcane, maize and wheat is an effective means of controlling BW of groundnut (Sun et al. 1981; He 1990). It is possible to minimise and even achieve near complete control of BW following rotation of groundnuts with paddy rice for 3–5 years (Wang et al. 1983; He 1990). Several groundnut–rice rotation systems are widely adopted in irrigated areas of Guangdong, Fujian, Hubei and Shandong provinces of China where the disease is a production constraint. In Guangdong Province of China, rotation of groundnut with sugarcane for 2–3 years has been found effective in reducing BW incidence from 60% to below 10% (OCRI 1977). In the Hubei Province, rotation of groundnuts with wheat is helpful in reducing wilt incidence in uplands. In drylands, rotation of groundnuts with maize, sorghum and sugarcane for longer periods (4–5 years) is useful in containing the disease. In such areas intercropping of groundnuts and maize can also be used as a means of reducing wilt incidence. Intercropping experiments in the Philippines showed that maize was the most effective of several intercrops in reducing BW disease incidence in potatoes (Kloos et al. 1987). Little is known as to how these cropping systems affect the perpetuation and survival of the BW pathogen.

Flooding of groundnut fields for 15–30 days before planting effectively reduces BW incidence (OCRI 1977; Li et al. 1981).

Some soil amendments such as S-H mixture, urea and mineral ash can be useful in reducing BW incidence (Chang and Hsu 1988; Sun and Huang 1985). The S-H mixture is very rich in calcium and silicon, and calcium is likely to enhance host resistance to wilt. Other components of S-H mixture may stimulate soil microbial activity against the wilt pathogen. Further

research is required to elucidate mechanisms of BW control following soil amendments.

Crop sanitation (e.g. burning of crop residues and removal of solanaceous weeds, and cleaning of tools and machinery after operations in infested fields) help reduce disease levels.

Concluding Remarks

The cultivation of wilt-resistant groundnut cultivars is highly useful in effective management of bacterial wilt. Over 60 germplasm lines have been identified as resistant to BW, and 20 wilt-resistant cultivars have been developed, mainly in China and Indonesia. It is imperative to broaden the genetic base of wilt-resistance by using different parents with high levels of stable resistance, including highly resistant wild *Arachis* species. International 'bacterial wilt nurseries' should be established to test stability of resistance and pathogen variability. Since rust and leaf spot diseases are severe in many areas where BW is a production constraint, priority should be given to incorporating resistances to bacterial wilt, rust and leaf spots into high-yielding cultivars adapted to specific environments. Further genetic evaluation of BW-resistance, involving several strains or pathotypes, is required to devise strategies for effective use of sources of resistance in breeding programs. Priority should be given to testing of selected resistant lines, including differentials, for their reaction to several strains or pathotypes of the pathogen from different regions of the world. This work should be possible in a country where groundnut is not grown and where *P. solanacearum* is not a problem. It is necessary to identify the most virulent strains so that they can be used for screening in breeding programs. Research efforts are needed to elucidate the mechanisms and components of wilt-resistance. Some cultural practices such as rotation with rice, maize or sugarcane and crop sanitation are effective in containing the disease. In irrigated areas or relatively high rainfall areas of southern Asia and Southeast Asia, crop rotation with paddy rice is feasible and is effective in reducing disease levels. More information is needed on the effects of different cropping systems and rotations on survival of *P. solanacearum*, and on the mechanisms involved in decreasing or increasing populations of the pathogen. Although sanitation practices are helpful in reducing disease levels, the impact of crop sanitation practices, particularly management of crop residues and weeds, on the BW pathogen and the disease needs to be demonstrated. The soil solarisation approach to wilt control should be investigated; this may prove effective in humid tropical countries. Emphasis should be placed on an integrated approach to bacterial wilt control, involving wilt-resistant cultivars, rotation with non-host crops (rice, sugarcane or maize), and crop sanitation.

Research on Bacterial Wilt of Groundnut in Vietnam

N.X. Hong* and V.K. Mehan†

Abstract

Recent systematic surveys of plant diseases in Vietnam indicate that bacterial wilt of groundnut is an important disease in the northern part of the country. The disease is particularly serious in several important groundnut-growing areas of Nghe Tinh Province. All *Pseudomonas solanacearum* isolates from wilt-affected groundnut plants from these areas were highly virulent to groundnut at 30–32°C. Most of these isolates were pathogenic to potato, tomato, and tobacco. Preliminary results indicated that the bacterial isolates belonged to race 1. Studies are in progress to determine the biovars of the wilt pathogen collected from various disease-affected areas. Identification of wilt-resistant groundnut germplasm and breeding lines is one of the major research thrusts at the National Institute of Agricultural Sciences. Some local cultivars which appear to be resistant to the disease in other countries were evaluated in bacterial-wilt hot spots in Vietnam and their reactions to the disease are discussed.

GROUNDNUT is the most important food legume crop in Vietnam where over 200000 ha are planted annually. The major groundnut-production areas are Nghe Tinh, Thanh Hoa, and Ha Bac provinces in northern Vietnam, and Tay Ninh, Song Be, Long An, and Dong Nai Provinces in the south. Average pod yield is about 970 kg/ha.

Diseases are major constraints of groundnut production in Vietnam, with bacterial wilt caused by *Pseudomonas solanacearum* one of the important diseases responsible for groundnut yield losses.

Systematic disease surveys conducted during 1990–1992 indicated that bacterial wilt of groundnut was present in all groundnut-growing provinces of northern Vietnam, but disease incidence varied greatly from place to place. The disease is particularly serious in several important groundnut-growing areas of Nghe Tinh and Thanh Hoa Provinces where plant mortality can be 15–35%. The disease is becoming increasingly important (20–30% plant mortality) in some areas of Long An and Tay Ninh Provinces of southern Vietnam.

*National Institute of Agricultural Sciences (INSA), Hanoi, Vietnam.

†International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Patancheru 502 324, A.P., India.

Research on bacterial wilt of groundnut is now being conducted mainly by the National Institute of Agricultural Sciences (INSA), Hanoi. This report summarises some of the research at INSA and outlines plans for future research.

Pathogen Isolation and Virulence

All *Pseudomonas solanacearum* isolates from wilt-affected groundnut plants collected from several disease hot spots in northern Vietnam were highly pathogenic to groundnut at 30–32°C. All isolates tested grew well on sucrose peptone agar (SPA) at 30–35°C. Most of these isolates were virulent to potato, tomato, eggplant and groundnut, but less virulent to tobacco. Extensive research is in progress to determine the biovars of the wilt pathogen collected from various disease-affected areas of northern Vietnam.

Host Resistance

In all groundnut-growing areas of northern Vietnam, the disease progress peaks at podding (65–70 days after sowing). Identification of wilt-resistant groundnut germplasm and breeding lines is one of the major research thrusts at INSA. Nineteen germplasm and breeding lines reported as resistant to bacterial wilt

in other countries were evaluated for resistance to *Pseudomonas solanacearum* in glasshouse tests using a root-inoculation technique. Two-week-old plants were inoculated with inoculum of a 48-hour culture of the bacterium grown on SPA medium. Seven of the 19 lines were highly resistant to isolates of the wilt pathogen tested (Table 1). These included four accessions of the cultivar Schwarz 21, a germplasm line (U4-47-7), and a breeding line (ICGV 87206). Two other breeding lines, ICGV 88271 and ICGV 88274, were moderately resistant to bacterial wilt. These breeding lines possess resistance to rust and late leaf-spot diseases. The cultivars Gajah, Matjan, and Kidang showed considerable wilt incidence. There were no marked differences between the isolates for wilt incidence in different cultivars/lines tested.

[a]ICG =ICRISAT Groundnut Accession Number and ICGV=ICRISAT Groundnut Variety Number.
[b] Local cultivar.

Some local cultivars such as Li and Tram Xuyen appear to be resistant to bacterial wilt under field conditions. Some breeding lines introduced from ICRISAT (e.g., ICGV 87157, ICGV 87206, ICGV 87165) have also been observed to show low incidence of bacterial wilt in hot spots. Thirty germplasm and breeding lines reported resistant to the disease in other countries are now being evaluated for field resistance to bacterial wilt in disease hot spots.

Future Plans

Intensive surveys will be carried out to assess the distribution and economic importance of bacterial wilt, particularly in southern Vietnam. Future research into stable genetic resistance to bacterial wilt, and incorporation of resistance to other yield-reducing diseases (e.g., leaf spots and rust) will be given high priority.

Control of Peanut Bacterial Wilt Through Crop Rotation

M. Machmud*

Abstract

A three-year crop rotation trial was done at Muara Experimental Farm, Bogor, in an effort to control bacterial wilt of peanut caused by *Pseudomonas solanacearum*. Two crops were grown annually: wet season and dry season crops. The rotation treatments consisted of time durations and crop combinations. The durations of rotations were one, two and three years. The crop combinations in each year were: peanut-peanut; peanut–maize; lowland rice–lowland rice, soybean–soybean, maize–soybean, and sweet potato–sweet potato. To eliminate variation due to planting season and crop combination, two trials were done: one was started in the WS 1987–88 and another in the DS 1988. Gajah, a resistant peanut cultivar (cv) was used in the rotation. Susceptible peanut cv. Kelinci and tomato cv. Gondol Hijau were used as indicator plants to assess the wilt intensity in each plot after the rotation. Generally the wilt intensity in plots treated with the different rotations was reduced. Three-year rotations could reduce wilt intensity from 64–12% on peanut cv. Kelinci and from 80–22% on tomato cv. Gondol Hijau. The longer the rotation period, the lower was the wilt intensity. Rotation of peanut with lowland or irrigated rice is the most effective in controlling the disease, followed by maize–soybean, maize–peanut, soybean–soybean, sweet potato–sweet potato, and peanut–peanut. A two-year rotation with a non–host crop such as rice or maize would be sufficient to control the disease. However, it needed a longer rotation period when resistant hosts such as sweet potato, soybean, or peanut cv. Gajah were used. This is probably because the resistant hosts could still harbour the pathogen. Crop sanitation from weed hosts, infected plant debris and avoidance of contaminated irrigation water from upstream also need to be attended to during crop rotation.

PEANUT is the second most important food legume in Indonesia. Its annual harvest area is approximately 550000 ha with production of 500000 t/ha. About 60% of peanut crops in Indonesia are grown under upland conditions, while the rest are irrigated or lowland crops. Peanuts are grown either as a monoculture or intercropped with other food crops such as maize and cassava.

Bacterial wilt caused by *Pseudomonas solanacearum* is an important disease of peanut in Indonesia. Since it was first reported by van Breda de Haan in 1905, the disease has been shown to be wide spread in the country. Despite various efforts to control it by Dutch and Indonesian scientists, such as through the development of resistant cultivars and the adoption of different cultural practices, the disease remains a major problem in peanut production (Machmud 1986).

*Bogor Research Institute for Food Crops (BORIF), Jl., Tentara Pelajar 3a, Bogor 16111, Indonesia.

The effectiveness of crop rotation to control bacterial wilt is not clear-cut (Kelman 1953). In some countries, such as Brazil (Robbs 1960), India (Sohi et al. 1981), Indonesia (Machmud 1986), and China; Wang and Hou 1982), bacterial wilt incidence in the field has been considerably reduced by rotation with irrigated rice or by flooding, but not in Sri Lanka (Seniveratne 1976). More recent reports suggest greater effectiveness of crop rotation in controlling the disease (He 1990; Shekhawat et al. 1988). Most trials reported, however, were done on crops other than peanut.

Except from China (He 1990) and Indonesia (Machmud 1986), there have been very few reports on the control of bacterial wilt of peanut, particularly through crop rotation. This is probably because bacterial wilt of peanut has so far been important only in these countries.

This paper reports results of a three-year crop rotation trial using resistant and non-host crops to control bacterial wilt of peanut.

Materials and Methods

The trial on peanut rotation with other food crops was conducted at Muara Experimental Farm, Bogor, in an area known to be heavily infested with *P. solanacearum* race 1. Duration periods of the rotation were 1, 2 and 3 years, but the whole experiment took 4 years to complete, from the wet season (WS) of 1987/88 to the dry season (DS) of 1992. Peanut cv. Kelinci and tomato cv. Gondol Hijau, both susceptible to bacterial wilt, were used as standard checks or indicator plants to determine the wilt incidence in the field before and after the rotation. The food crops used in the rotation were peanut cv. Gajah (resistant to bacterial wilt), soybean cv. Orba, maize cv. Arjuna, lowland rice cv. Cisadane, and sweet potato cv. Borobudur. In each rotation period, two crops were grown, one following another. One crop was grown in the wet season (October–February), the other in the dry season (April–August). The crop combination patterns were: peanut–peanut; peanut–maize; rice–rice; soybean–soybean; maize–soybean, and sweet potato–sweet potato. To eliminate variation due to effect of planting season and crop combination, two trials with exactly the same treatments were arranged. One trial was initiated in the WS 1987–88, the other in the WS 1989–90. The two trials were close to each other.

Before laying out the trial, peanut cv. Kelinci and tomato cv. Gondol Hijau were grown in the experimental site to check the intensity of the bacterial wilt and provide a more uniform pathogen distribution. After assessment of the wilt intensity, the plants were ploughed under to spread inoculum of the pathogen uniformly and 2.5 m × 5 m plots were made. Drainage canals and ditches were made between plots to prevent flood or irrigation water running from one plot to another. During the rotation, peanut and soybean plants were grown in a 40 cm × 15 cm spacing, one plant per hill. Maize, sweet potato, and rice plants were grown in 50 cm × 100 cm, 50 cm × 50 cm, and 20 cm × 20 cm spacings, respectively. The rice plants were grown under irrigated or lowland condition. Crop treatments, such as fertiliser application, weeding, and insect control were done accordingly. After harvesting the first crop, the land was cleared and prepared for the second crop. After the second crop, 100 seeds of peanut cv. Kelinci and 100 seedlings of tomato cv. Gondol Hijau were grown alternately in each of the plots with one-year rotation treatment. Bacterial wilt incidence in these plots was assessed from the wilt intensities on both indicator plants four weeks after planting. For the two- or three- year rotation treatments, after harvest of the second crop, the plots were subsequently grown with the second-year rotation crops. The indicator plants were grown again after every rotation period.

The experimental design of each trial involved a split plot with two replications. The main plots were the periods of rotations and the sub plots the crop combinations.

Results and Discussion

The field which was used for the rotation trial had been planted continuously for 2–3 years with peanuts as a monoculture or intercropped with other food crops. The bacterial wilt intensities on susceptible peanut cultivars, such as Kelinci and Landak, were always high (60–70%). When the field was grown with the susceptible indicator hosts, peanut cv. Kelinci and tomato cv. Gondol Hijau, before the rotation trial, the wilt intensities were 64% and 80%, respectively. During the trial, the wilt intensities on the indicator hosts grown in plots with no rotation were consistently high, ranging from 60–66% on cv. Kelinci and 80–83% on cv. Gondol Hijau. The data also indicated that, under the Muara Experimental Farm's conditions, the season the crop rotation was started did not affect wilt intensity in the field (Table 1). This is probably because agroclimatic conditions in this area did not vary significantly, particularly with regard to seasonal rainfall and soil relative humidity, and were conducive to development of the disease.

After the rotations with the different crops and crop combinations, including that with resistant peanut cv. Gajah, bacterial wilt incidence in each plot was reduced. The wilt reduction varied with the crop combinations used in the rotation as well as with the duration of the rotation (Table 1). However, the wilt intensities in all plots treated with the different rotation combinations were continuously reduced when the rotation period was lengthened from 1–3 years. After 1 year of rotation, the wilt intensities on peanut cv. Kelinci were reduced from an average of 60% to a range from 58–33%. The reduction was highest when the rotation was with lowland rice, followed by rotation with maize–soybean, peanut–maize, soybean–soybean, peanut–peanut, and sweet potato–sweet potato. In the second year, the wilt intensities ranged from 21% on plots with lowland rice combination, to 47% on plots with peanut cv. Gajah or sweet potato combination. After the third year of rotation, the level of wilt intensities on plots with lowland rice combination was still the lowest (Table 1). The ranking of effectiveness of the crop combinations used in the rotation in reducing the bacterial wilt intensities were, in order, lowland rice, followed by maize, soybean, resistant peanut, and sweet potato.

The variabilities of effectiveness in reducing the bacterial wilt intensities were probably due to inability of the bacterium to multiply and infect the plants. Granada and Sequeira (1983), however, stated that a

[b]Check plots were plots which are continously grown with susceptible peanut cv. Kelinci.

particular crop may be a non-host to *P. solanacearum*, but susceptible in the presence of interacting nematodes. Such a phenomenon may overide any effect on pathogen suppression. This might have happened when sweet potato, soybean or peanut cv. Gajah was used in the rotation. In Vietnam, however, soybean has been reported susceptible to bacterial wilt (Tung 1986). He (1990) also reported from China that the sweet potato strains of the bacterium were able to infect groundnut and those from groundnuts could infect sweet potato.

Symptomless infection could occur on resistant hosts or nonhost plants such as weeds. This has been shown on alligator weed, *Portulaca oleracea* (Hayward and Moffett 1978). It is therefore important to carry out crop sanitation during rotations.

The effectiveness of peanut rotation with lowland rice confirmed previous reports from Indonesia (Machmud 1986) and China (He 1990; Wang and Hou 1982). He (1990) reported that flooding of groundnut fields for 15 days before planting was effective in reducing bacterial wilt incidence. Other monocots that have been used successfully in controlling bacterial wilt by crop rotation are wheat and barley (He 1990; Shekawat et al. 1988), sugarcane and sorghum (He 1990; Wang and Hou 1982). Apart from the fact that they are non-hosts to the bacterium, monocot crops are generally also highly competitive against weeds that may act as alternate hosts for *P. solanacearum* or nematodes. Non-host dicots that have been reported to reduce bacterial wilt intensity are cowpea, cabbage, okra and radish (Sohi et al. 1981), particularly on tomato and eggplant.

The optimum time for rotation may also be affected by several interacting factors, such as strains of the pathogen present, environmental conditions and soil types. Under Muara Experimental Farm conditions, at least a two-year rotation with lowland rice is necessary to significantly reduce the effect of bacterial wilt. In China, two- to five- year periods of rotation are generally needed for an adequate reduction of bacterial wilt caused by race 1 (He 1990).

Conclusion

Rotation of a susceptible peanut cv. Kelinci with resistant peanut cv. Gajah, maize, lowland rice, soybean, or sweet potato reduced wilt intensities in the field. Peanut rotation with irrigated lowland rice is the most effective way of controlling bacterial wilt,

followed by rotation with maize, soybean, resistant peanut, and sweet potato. A longer rotation period of from one to three years, resulted in a lower wilt intensity. Two-year rotation of peanut with lowland rice is generally sufficient to reduce the disease considerably.

Acknowledgment

This work has been done as a part of the AARD-ACIAR collaborative research program between the Agency for Agricultural Research and Development (AARD), Indonesia, and the Australian Centre for International Agricultural Research (ACIAR) through ACIAR Project No. 8834 (Strengthening of peanut production in Indonesia). The author wishes to acknowledge the valuable suggestions and encouragement of Mr Keith Middleton, Queensland Department of Primary Industries, Australia.

Bacterial Wilt of Groundnuts in Malaysia

S. Hamidah* and K.Y. Lum†

Abstract

Local production of groundnuts in Peninsular Malaysia has declined from some 20000 t annually in the 1980s to 5000 t currently, primarily as a result of a reduction in planted areas. The two major production areas are in the States of Kelantan and Terengganu on the east coast of Peninsular Malaysia, where the incidence of bacterial wilt on the crop has remained high. Information on bacterial wilt of groundnuts is being gathered through collection and identification of isolates from plants. Results from a resistance screening program involving ICRISAT accessions and Indonesian and local varieties have shown that selected lines do not perform consistently when subjected to field trials under local situations. These observations, together with laboratory characterisation of some bacterial wilt isolates, suggest the existence of different local pathogenic strains.

BACTERIAL wilt of groundnuts caused by *Pseudomonas solanacearum* is the only important bacterial disease of groundnuts (Mehan et al. 1986). The potential threat of the disease is very real, especially in the warm humid regions of the world where groundnuts are grown. In Malaysia, the majority of groundnut farms are smallholdings in Kelantan (1219 ha), Terengganu (242 ha), Perak (252 ha), and Kedah and Perlis (82 ha). The total area sown to groundnuts declined from 5197 ha in 1980 to 1318 ha in 1986. Total production similarly decreased, from 19437 t to less than 5000 t within the same period. However, the net demand for the commodity is on the increase. In 1986, imports of groundnuts totalled 44871 t with a value of MR 29.7 million, mainly in the form of shelled nuts, with smaller amounts as groundnut oil and oil cake residues for livestock feed. Major exporters to Malaysia are Vietnam, United States, China, Thailand, Taiwan and Hongkong. However, Malaysia also exports groundnuts in the form of canned and uncanned nuts to a value of MR 5.8 million.

The decline in production is attributed to the high cost of production, particularly for labour, unfavourable yield levels and high incidences of bacterial wilt disease in the two major production areas in Kelantan and Terengganu. The pathogen affects a whole range of crops in the country, but information on the pathogen attacking groundnuts is scanty. Schwarz (1926), in rotation trials with groundnuts, tobacco, potato, tomato and eggplant, attributed differing wilt disease incidences to strain differences in the pathogen. Various other reports (McClean 1930; Dowson 1949; Kelman and Person 1961; He et al. 1983) suggest the existence of pathogenic strains. Pathotypes associated with particular geographical locations have also been suggested (Buddenhagen and Kelman 1964; Simbwa-Bunnya 1972). Tan and Liao (1990) reported evidence that strains of groundnut bacterial wilt differ in their pathogenicity to the same host cultivar in different parts of China.

Materials and Methods

Screening for bacterial wilt resistance

In collaboration with ICRISAT, groundnut lines were screened for resistance to bacterial wilt at a number of localities. Typically, 20 seeds of each groundnut line were planted at 10 cm × 50 cm spacing, together with the susceptible checks, Gajah, Matjam and MKT1. Recordings for disease incidence as a result of natural infection were taken 4 weeks after planting. Trials were generally replicated thrice and carried out in plots

situated in Kelantan and Kedah. In another trial at Serdang, plants were artificially inoculated using the multi-pinprick method with isolates collected from groundnut-growing areas of Kelantan and Terengganu. Percentage of plants wilted was recorded one week after artificial incoulation.

Characterisation of isolates

Isolates of *P. solanacearum* were identified using GN plates of the BIOLOG microbial identification system (Biolog Inc., Hayward, California, USA.). Four typical groundnut isolates were compared with an isolate from tomato. Isolates GN1-4 were from groundnut and obtained from Pasir Mas, Kelantan, except for GN-4 which came from Serdang, Selangor. The T-1 isolate from tomato originated from Serdang, Selangor.

These isolates were also inoculated onto groundnut cultivar MBT 91-2 and disease progression compared. Each isolate was inoculated onto 20 plants, each plant receiving a dose of 50 µL of the appropriate bacterial suspension set at a fixed concentration (0.15 O.D. at 590 nm) and delivered with a calibrated micropipette.

Results and Discussion

Screening for bacterial wilt resistance

Screening results of the ICRISAT lines and local checks differed in their response to infection (Table 1). While reliance on natural inoculum meant lower infection percentages, there were differences in the performances of the check cultivars at the two different localities of Kelantan and Kedah. Artificial inoculation caused higher infection percentages, and in some cases were in direct contrast to natural infection results. This reinforces the need for detailed evaluation of host materials over time and locations to determine more precisely the performance of host material.

Characterisation of isolates

The tomato isolate was more virulent on groundnut cultivar/line MBT 91-2 (= ICGU 86188) than the four groundnut isolates (Fig. 1). Tomato isolate caused plants to wilt more rapidly although at 12 days after inoculation more than 88 % of the plants inoculated with either T-1, GN-1 or GN-2 had similar levels of wilt. The isolates GN-3 and GN-4 were less virulent than the others.

Using the BIOLOG characterisation, groundnut isolates were classified as '*P.solanacearum* A' and the tomato isolate as '*P.solanacearum* B'. Comparison of the ninety-five tests which formed the BIOLOG GN plate system indicated a number of key differences in the pattern of utilisation of substrates between the isolates (Table 2). It was also noted that although there were variations between the four groundnut isolates themselves, the tomato isolate differed from the four in the utilisation pattern for a number of substrates.

Breeding for Resistance to Bacterial Wilt of Groundnuts in Uganda

C.M. Busolo-Bulafu*

Abstract

While groundnut (*Arachis hypogaea*) is the second most widely grown grain legume in Uganda, various factors have lowered productivity of groundnut crops by interfering with plant growth and development. One of the diseases gaining in importance on groundnuts in Uganda is bacterial wilt caused by *Pseudomonas solanacearum*. Research efforts have emphasised breeding for resistance to the disease and preliminary results have identified a number of promising genotypes including RMP-12, AT4 74/3/5/4, AT5 138/2/3/3, AT5 139/6/4/1 and AT4 74/3/35/3.

BACTERIAL wilt disease caused by *Pseudomonas solanacearum* E.F. Smith has been observed in some areas of central (Lake Crescent) and northwestern Uganda. The disease has undoubtedly been present on groundnuts in the country for many years. It was first diagnosed on groundnuts in Uganda at Bukalasa in 1938 by Hansford and reported to have caused 10% loss of the crop. Simbwa-Bunnya (1972) reported up to 60% losses in 1963. Bacterial wilt is known to attack several other crops in Uganda, including tomatoes, tobacco, eggplants, and potatoes.

Groundnut cultivars differ in their reaction to the disease. The Red Valencia type cultivars are highly susceptible. These are the varieties preferred by the great majority of the people in Uganda, especially in the Central Region. In general, the spreading types appear to be less susceptible. The disease is particularly associated with partially waterlogged soils and the causal bacterium seems to be spread on the surface of water.

It has been suggested that the disease may be seedborne in groundnuts and, for this reason, it has been departmental policy to discourage the distribution of any seed for planting from areas where the disease is known to occur in Uganda. Nevertheless, because of free movement of groundnut seed by traders to various markets in the country, the disease could be of wider distribution than is presently known.

*Groundnut Breeder, Namulonge Research Station, PO Box 7084, Kampala, Uganda.

Control of bacterial wilt has been quite difficult due to the fact that it is soilborne, thus making chemical control ineffective. Other control methods, such as crop rotation, biological control and soil amendments, have been tried with limited success in some countries. Breeding for disease resistance is likely to be the most effective means of control, at least in Uganda.

Several sources of resistance are available and these include RMP-12, AT4 74/3/5/4, AT5 261/5/2/8, AT4 74/3/5/3 and AT4 107/2/4/3. Some hybridisation work was carried out in 1973 to incorporate resistance into the popular but susceptible varieties. Screening work on some germplasm, including those mentioned above was reactivated at Namulonge Research Station recently. This screening is currently being carried out in the field, but glasshouse screening using artificial inoculation is also being considered.

Materials and Methods

The varieties were evaluated at Namulonge Research Station and Bukalasa Variety Trial Centre (VTC) under field conditions during the first rainy season of 1991. Variety B1 was included as the susceptible check and Roxo as the commercial variety. The experimental design was the randomised complete block design (RCBD) with five replications. Each plot consisted of six rows, 5 m long and 60 cm apart. Observations were made on the wilted plants commencing 2–3 weeks after emergence and their wilt intensities counted. Yield data were also collected.

[a]Column means followed by the same letter(s) do not differ significantly at the 5% level of probability ($P < 0.05$) according to Duncan's Multiple Range Test.

Results and Discussion

Significantly higher yields were obtained from seven lines (A, C, F, G, H, I and J) over the control (B1), while three lines (A, H and I) significantly outyielded the commercial variety, Roxo, at Bukalasa (Table 1). At Namulonge only two lines (C and I) had significantly higher yields than B1. Ratings for bacterial wilt indicated that lines C, I and J were least susceptible, though all the selections were quite resistant. However, the lines have to be tested using standard glasshouse procedures in order to ascertain the resistance levels.

Molecular Basis of Virulence and Pathogenicity

Studies of the *Hrp* Pathogenicity Genes from *Pseudomonas solanacearum* GMI1000

M. Arlat, F. van Gijsegem, S. Genin, C. L. Gough, C. Zischek, P.A. Barberis and C. Boucher*

Abstract

Hrp genes are essential for the ability of the *Pseudomonas solanacearum* strain GMI1000 to be pathogenic on tomato and to induce a hypersensitive response (HR) on tobacco. These genes are known to be clustered in a region of about 23 kb of the genome. DNA sequencing of 20 kb of this cluster led to the identification of 19 genes, six of which share homology with essential pathogenicity genes from the animal and human pathogens *Yersinia pestis*, *Y. enterocolitica* and *Shigella flexneri*. Based on these homologies we predicted that an *hrp*-dependent HR-inducing factor should be produced in the supernatant of *P. solanacearum* cell cultures. Preliminary experimental data suggest that such a factor does exist as a heat-resistant protein released into the culture medium via an *hrp* gene encoded secretion machinery. We also report on the DNA homologies existing between *hrp* genes from *P. solanacearum*, *P. syringae*, *Xanthomonas campestris* and *Erwinia amylovora*.

BASED on the economic losses caused worldwide, *Pseudomonas solanacearum* E.F. Smith is considered one of the most important plant pathogenic bacteria (Hayward 1991). This results not only from the broad geographical distribution of this bacterium which includes tropical and subtropical areas of the globe but also from an unusually wide host range that includes a large number of major agricultural crops. The economic importance of the disease also reflects the limited means of protection currently feasible, these being mostly restricted to certain farming practices and the use of resistant varieties when available.

The precise identification of the biochemical determinants of pathogenicity for this organism, and definition of their respective roles in disease development, is clearly needed in order to understand the mechanisms underlying the pathogenicity processes. This approach, aimed at a further understanding of the key factors determining plant bacteria interactions, should allow new methods of disease control to be developed by interfering with the normal course of the infection process.

*Laboratoire de Biologie Moléculaire des Interactions Plantes-Microorganismes, CNRS-INRA, Chemin de Borde Rouge, BP 27, 31326 Castanet Tolosan cedex, France.

Genetics and molecular biology offer powerful tools for deciphering elementary steps occuring during plant–bacterial interactions. Using this approach, and starting from a wild-type fully pathogenic strain, it is possible to create mutants affected in pathogenicity or in the ability to induce a hypersensitive response which differ from the wild-type parent by the inactivation of a single gene. This approach allows an unambiguous identification of genes playing an important role in disease development. Once identified, these genes can be cloned (physically isolated from the rest of the genome) and then studied to determine the biochemical functions they encode and the mechanisms governing regulation of their expression.

In the last decade this approach has been used to identify important pathogenicity genes of *P. solanacearum* and to re-examine the possible role of certain bacterial compounds, including extracellular hydrolytic enzymes and exopolysaccharides, in disease development. Most of this work has been reviewed recently (Boucher et al. 1992; Denny and Schell 1992).

In our laboratory we have identified a cluster of genes, called *hrp*, which is required both for disease development on compatible hosts and for the elicitation of the hypersensitive response (HR) on non-host plants (Boucher et al. 1988). These genes have been found in

all pathogenic strains studied (Boucher et al. 1988; Cook et al. 1989). Further characterisation of these genes has been achieved in our laboratory using strain GMI1000. This strain induces a typical HR following infiltration into tobacco leaf parenchyma and is fully pathogenic on tomato. Most of its *hrp* deficient derivatives have lost the HR-inducing activity and have become nonpathogenic on tomato irrespective of the inoculation procedure used and the developmental stage of the inoculated plants. However, mutations occurring in the far right-hand-end of the cluster led to 'leaky' mutants which only induced a weak and/or delayed HR and displayed a weak aggressivity toward tomato. *Hrp* mutants that were non-pathogenic on tomato did, however, retain the ability to penetrate tomato plants and to colonise the stem. Nevertheless, in these infected plants the bacterial population remained at least two orders of magnitude lower than in plants infected with the wild-type parental strain (Trigalet and Démery 1986).

The *hrp* genes in strain GMI1000 are organised in at least six transcription units covering about 23 kilobases (kb) of the genome (Arlat et al. 1992). This region is carried on the megaplasmid of greater than one megabase which has been shown to be present in this strain (Boucher et al. 1986). Previous studies have also established that the majority of *hrp* genes are not expressed during culture of the bacterium in a peptone-containing medium but that expression occurs following inoculation on plants or during growth in minimal medium (Arlat et al. 1992).

Although the *hrp* region is now physically well-defined, the identification of individual genes within this region and the characterisation of the biochemical and physiological functions encoded by these genes remains to be done. Recent data obtained in our laboratory and reported in this paper contribute significantly to the achievement of this goal.

Identification of Individual *Hrp* Genes within the Cluster

We have recently proposed that the *P. solanacearum* *hrp* gene cluster is organised within a minimum of six transcription units (Arlat et al. 1992). DNA sequencing of 20 kb spanning the four transcription units located at the left-hand-end of the cluster had led to the identification of 19 open reading frames (ORFs) which have a high coding probability as deduced from codon usage. The relative position of these ORFs within the cluster, together with the proposed nomenclature for the corresponding genes, is presented in Figure 1. This organisation is in agreement with the previously proposed transcriptional organisation of this region (Arlat et al. 1992). Analysis of the amino acid (aa) sequences of the predicted proteins has revealed that 7 of them contain putative transmembrane alpha helix domain(s) and could therefore be located in the membrane (Fig. 1).

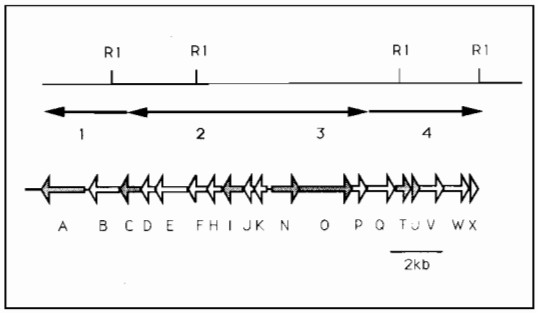

Fig. 1. Genetic organisation of the *hrp* gene cluster: top line is an EcoR1 (R1) restriction map of the left end of the cluster. Solid arrows show the individual transcription units. Open arrows at the bottom of the figure represent the individual open reading frames for the putative *hrp* proteins. When a protein is predicted to have transmembrane domain(s) the corresponding arrow is shaded.

HrpB Codes for a Positive Regulator

The *hrpB* gene has a coding capacity for a 477 aa peptide. This putative peptide shows significant similarity to several procaryotic transcriptional activators (Genin et al. 1992) including the AraC protein of *Escherichia coli* (Migula) Castellani and Chalmers (Wallace et al. 1980), the XylS protein of *P. putida* (Trevisan) Migula (Mermod et al. 1987) and the VirF protein of *Yersinia enterocolitica* (Schleisfstein and Coleman) Fredericksen (Cornelis et al. 1989). The *hrpB* gene product therefore belongs to a different family of bacterial regulators to that described for the *HrpS* protein of *P. syringae* pv. *phaseolicola* (Burkholder) Young et al. (Grimm and Panopoulos 1989). Genetic evidence demonstrates that during growth in minimal medium, the *hrpB* gene product actually acts as a positive regulator for the expression of transcription units 2, 3 and 4 of the *hrp* gene cluster (Fig. 2) (Genin et al. 1992).

In addition, the introduction of *hrpB* into *P. solanacearum* using the multicopy plasmid vector pLAFR3 also resulted in an increased level of transcription unit 5 when bacteria were grown under inducing conditions.

The *hrpB* gene also controls the expression of additional genes located to the left of the *hrp* gene cluster, for which no involvement in plant–bacteria interactions has yet been identified (Genin et al. 1992). Finally, we have established that expression of *hrpB* is partly self-activated, although dependent on additional regulatory factor(s).

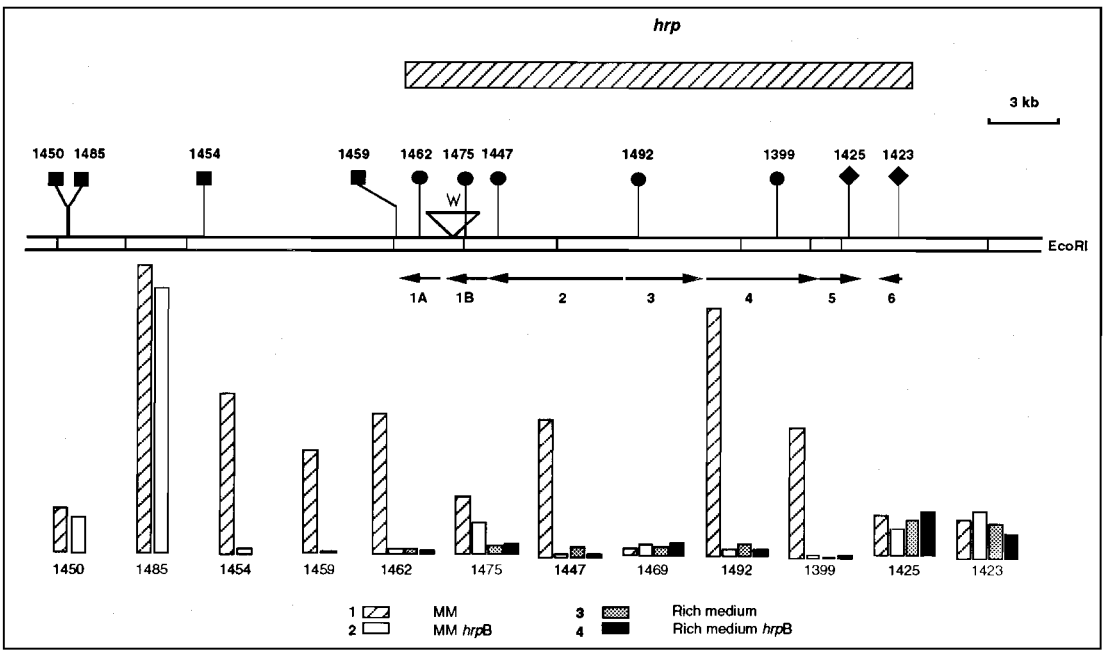

Fig. 2. Regulation of *hrp* gene expression and flanking regions by *hrpB*: The top of the figure represents the EcoRI restriction map of the *hrp* gene cluster and of the left flanking region together with the localisation of the lacZ reporter gene fusions which have been generated using transposon Tn5-B20 (Arlat et al. 19 92). The triangle above the map shows the location of the insertion of the omega interposon generating a *hrpB* mutation. Histograms represent the relative level of expression of each gene fusion under inducing conditions in the wild-type (1) versus a *hrpB* mutant background (2) and in rich medium in the wild-type (3) versus a *hrpB* mutant background (4) respectively.

Homologies between *Hrp* Genes and Genes Governing the Production of Extracellular Pathogenicity Factors in Animal and Human Pathogens

Comparison of the aa sequence of the putative *hrp* proteins with protein sequences present in various data banks revealed that, in addition to *hrpB*, at least five other *hrp* proteins showed clear homology with proteins of the human and animal pathogens *Yersinia pestis* (Lehmann and Neumann) Van Loghem, *Y. enterocolitica* and/or *Shigella flexneri* Castellani and Chalmers (Gough et al. 1992).

- *HrpA* codes for a putative protein of 568 aa which is 34% identical over its entire length to the YscC protein of *Y. enterocolitica* (Michiels et al. 1991).
- *HrpE* codes for a putative 439 aa protein which is 44% identical to the putative Spa47 protein of *Shigella flexneri* (Venkatesan et al. 1992).
- *HrpI* codes for a putative lipoprotein of 269 aa which is 35% identical over its entire length to the YscJ lipoprotein of *Y. enterocolitica* (Michiels et al. 1991).
- *HrpO* codes for a putative protein of 690 aa which is 43% identical to the LcrD protein from *Y. pestis* (Plano et al. 1991) and 34% identical over 690 aa to VirH protein of *S. flexneri* (Sasakawa, unpublished, Gene Bank accession D10999).
- *HrpQ* codes for a putative protein of 355 aa which is 26% identical over 69 aa to the sequenced part of ORF *spa33* of *S. flexneri* (Venkatesan et al. 1992).
- *HrpT* codes for a putative protein of 218 aa which is 40% identical to the putative protein encoded by the *spa24* gene of *S. flexneri* (Venkatesan et al. 1992).

Interestingly, *Yersinia* and *Shigella* mutants defective for these proteins are nonpathogenic and have lost the ability to release certain extracellular proteins (called Yops for *Yersinia* or Ipas for *Shigella*) which act as primary determinants of pathogenicity on host cells (Goguen et al. 1984; Michiels et al. 1991; Halle 1991).

It is assumed that, in these organisms, the proteins homologous to *hrp* proteins are constituents of a secretory machinery specifically involved in the transmembrane transport of Yops and Ipas. Based on these homologies and the fact that most *hrp* mutants were totally non-pathogenic, we postulated that *hrp* genes might be involved in the secretion of essential pathogenicity protein(s) which would be directly active on plant cells. The following data tend to support this hypothesis.

P. solanacearum Produces an HR-like Inducing Factor in Culture Supernatants

When the wild-type strain GMI1000 was grown in conditions that allow *hrp* gene expression (minimal medium with glutamate as sole carbon source) (Arlat et al. 1992), it was possible to detect an HR-like inducing activity in the non-dialysable fraction (MW > 10000) of a 20-fold concentrate of the supernatant. This activity occurred following infiltration into tobacco leaf parenchyma and subsequent incubation for 24–48 hours at 25°C. It resulted in the development of a necrotic lesion restricted to the infiltrated tissues which was highly reminiscent of the reaction induced by live bacteria both with respect to the kinetics of the response and the aspect of the necrotic lesions. Such activity was not found in the supernatant of any of the *hrp* mutants which mapped in transcription units 1 to 4, thus indicating that this activity was *hrp*-dependent and not the result of a nonspecific toxic effect of the supernatant on plant tissues. This activity was still present in the supernatant of mutants mapping in transcription units 5 and 6 which had previously been shown to retain a partial HR-inducing activity.

The activity present in the supernatant of the wild-type strain GMI1000 is assumed to be due to the presence of a heat stable protein(s), since it was resistant to heating for 8 minutes at 100°C but could be removed by treatment with proteinase K.

Possible Involvement of *Hrp* Genes in Controlling Secretion of the HR-like Eliciting Factor

Although no HR-like inducing activity could be detected in the supernatant of any of the *hrp* mutants that mapped in transcription units 1 to 4, an activity was found in filter-sterilised, sonicated cell lysates prepared from most of the *hrp* mutants, tested as well as from the wild-type strain. However, the two *hrpB* mutants tested which failed to produce a functional *hrp* positive regulator, had no intracellular activity, indicating again that this activity does not result from a nonspecific toxic effect of the cell lysate, but rather that is *hrp* gene specific. Similar to the extracellular activity, the intracellular activity was found to be heat-resistant and sensitive to proteinase K indicating that both intra- and extra-cellular activities could be due to the same protein(s) present both within and outside the bacterial cells. If this is true, our data relate in a similar way to *Yersinia* or *Shigella* counterparts, as several *hrp* genes are involved in the transport through the bacterial cell envelopes of extracellular protein(s) which, in the case of *P. solanacearum*, have a HR-like inducing activity.

The requirement of a functional *hrpB* gene for the production of the intracellular activity suggests that the structural gene(s) coding for the active compound(s) is part of the *hrp* gene regulon. However, since all the other mutants which map within the *hrp* gene cluster had retained an intracellular activity, it is most probable that this gene(s) map(s) outside of the *hrp* gene cluster.

Hrp Genes from *P. solanacearum* Share Homology with *Hrp* Genes from Other Gram-Negative Plant-Pathogenic Bacteria

We previously established that *hrp* genes from strain GMI1000 have a functional counterpart in all of the 90 virulent strains of *P. solanacearum* tested, irrespective of their race, biotype, or geographical origin (Boucher et al. 1988; Cook et al. 1989). Similarly, the *P. solanacearum hrp* gene cluster has been shown to hybridise with genomic DNA from all of eight pathovars of *Xanthomonas campestris* (Pammel) Dowson tested (Boucher et al. 1987). It has further been demonstrated that in *X. campestris* these homologous sequences correspond to functional *hrp* genes required both for pathogenicity and for HR induction (Arlat et al. 1991). Based on functional characteristics, the presence of *hrp* genes has been established in various pathovars of *P. syringae* and in *Erwinia amylovora* (Burrill) Winslow which was reviewed by Willis et al. (1991). However, it remains to be determined whether certain of these genes were homologous to *P. solanacearum hrp* genes. Because we have shown that several *hrp* genes are conserved in animal and human pathogens, this prompted us to investigate whether certain of these conserved genes may also be common to other plant pathogenic bacteria. To this aim, DNA probes consisting of internal fragments of *hrpA*, *hrpI* and *hrpO* were hybridised against Southern blots of genomic DNA of *X. campestris* pv. *campestris*, *P. syringae* pv. *phaseolicola* and *E. amylovora*, and against the corresponding cloned *hrp* gene clusters (Gough et al. 1992). The experimental results established that the conservation of all three *Hrp* genes in *X. campestris* and the conservation of *hrpO* in both *P. syringae* and *E. amylovora* had occurred.

Discussion and Conclusions

We have shown that in *P. solanacearum* the *hrp* genes are involved in the production and transport through the bacterial cell envelope of a compound that mimics the ability of live bacteria to induce an HR following infiltration into tobacco leaves. Although the role of *hrp* genes in controlling a secretion process remains to be clearly established, the discovery that a plant pathogenic bacterium produces an extracellular signal that is sufficient to induce an HR-like reaction sheds new light on our understanding of plant–pathogen interactions. Preliminary characterisation of this active compound has been achieved. Since it was nondialysable and sensitive to proteinase K it was assumed to be a protein. The question remains as to whether the activity observed on tobacco was due to a single factor, or whether several factors with a similar activity are involved. Purification and biochemical characterisation of the active compounds(s) is under way and should lead to the identification and cloning of the corresponding structural gene(s).

The next step will be to understand the mode of action of such compounds on plant cells. A preliminary goal will be to determine whether only one or several HR-like inducing factors are produced by the bacterium and whether these compounds are individually active on a limited or a large number of plant species. Of particular importance in this respect, will be the knowledge of whether there is a differential effect of these factors on host versus non-host plants.

Having purified and characterised the HR-like inducing factor(s), it will become possible to study their mode of action and to identify the corresponding targets present in the plant.

We have previously reported the conservation of *hrp* genes between *P. solanacearum* and *X. campestris* (Boucher et al. 1988; Arlat et al. 1991). Here we show that, in addition to the conservation between these two organisms, at least one of these genes is conserved in *P. syringae* and *E. amylovora*. Recent reports based on DNA sequence analysis of *hrp* genes from *X. campestris* pv. *vesicatoria* and *P. solanacearum* established the existence of *hrp* proteins homologous to the *hrpA*, *hrpE*, *hrpI* and *hrpO* proteins of *P. solanacearum* (Fenselau et al. 1992; Gough et al. 1992).

Huang et al. (1992) have also reported on the characterisation of two *hrp* genes from *P. syringae* pv. *syringae*. These genes are homologous to *hrp*A and *hrp*O (data not shown). Moreover it has recently been reported (Wei et al. 1992) that one of the *hrp* genes of *E. amylovora* codes for a heat stable protein that induces an HR following infiltration into tobacco leaf parenchyma. The corresponding structural gene has been sequenced and shown to encode a glycine-rich, 44 kb protein. To date, no gene encoding a homologous protein has been found within the sequenced part of the *hrp* gene cluster of *P. solanacearum*. This observation together with (i) the existence of common *hrp* genes, (ii) the similar size of the *hrp* gene clusters in these different organisms and (iii) the similar changes in certain biological traits related to bacteria–plant interaction and associated with mutations in the *hrp* genes, indicates that a common core of essential pathogenicity genes is shared among representatives of most Gram-negative plant pathogenic bacteria. This is an indication that, independent of the host-range and of the type of symptoms they can induce (i.e., wilt, necrosis, maceration or chlorosis), most Gram-negative plant pathogenic bacteria have developed a common strategy of plant infection. It is intriguing that this strategy is also shared by certain animal and human pathogens belonging to the genus *Yersinia* and *Shigella*. This raises the question as to how the corresponding genes have evolved in order to be present in such taxonomically distant organisms.

In addition to these common *hrp*-encoded pathogenicity functions, it is clear that each individual pathogen must have a set of specific genes controlling functions such as the production of toxins, hydrolytic enzymes or plant growth hormones which are probably directly responsible for the type of symptoms each organism induces on its own host plant(s). Nevertheless, phenotypic expression of these specific functions appears to be strictly dependent on the presence of a fuctional core of *hrp* genes.

The identification of a set of common pathogenicity genes among the vast majority of plant pathogenic bacteria and the characterisation of an extracellular HR-like inducing signal released by the bacteria open new perspectives in our understanding of the interactions of pathogens with plants. Moreover, since *hrp* genes are conserved between the individual species under study, it is clear that new information obtained on one model will be readily transposable to the others. Due to this cumulative effect, rapid progress should be made in understanding the basic mechanisms of pathogenicity towards plants. Therefore, one can predict that, in the near future, such knowledge should lead to the conception of new strategies for plant protection.

Analysis of Polygalacturonase as a Component of Bacterial Wilt Disease

C. Allen, L. Simon, M. Atkinson and L. Sequeira*

Abstract

Pseudomonas solanacearum produces at least three extracellular polygalacturonases (PG). An *endo*-PG of pI 9.2 (PehA) is produced abundantly when *P. solanacearum* grows in rich culture media, but has been shown to play only a minor role in disease development. Two *exo*-PGs of pI 7.2 (PehB) and 4.9 (PehC) were barely detectable when the bacterium was grown in rich culture medium, but were produced at much higher levels when the bacterium was grown *in planta*. Two mutant strains unable to produce PehB or PehC, respectively, were substantially reduced in virulence relative to the wild type strain. These results suggest that *exo*-PG, which is induced *in planta*, is a significant virulence component for *P. solanacearum*. Expression of the PG structural genes was controlled at the transcriptional level by a positive trans-acting regulatory locus called *pehR*. While *pehR* was required for *pehA* expression above basal levels, *pehB* mutants still produced *exo*-PG at about 50% of wild type levels. *pehR* mutants exhibited reduced virulence similar to that of the *exo*-PG mutant strains. In addition, *pehR* mutants exhibited reduced phosphorylation of an 85 kb membrane tyrosine phosphoprotein. DNA sequence analysis of the *pehR* region indicated that it has homology to several prokaryotic environmentally-responsive two-component regulators.

MANY papers about bacterial wilt mention that the physiological basis of wilt is poorly understood. Recently, several research groups have isolated various genes for factors believed to contribute to pathogenesis by *Pseudomonas solanacearum*. Using the powerful and highly specific tools of mutagenesis, cloning, and sequencing, we have identified many genes whose products or actions are required for normal disease development. Some of these products, such as extracellular polysaccharide (EPS), may be indispensable for disease; however, EPS alone is probably not sufficient to explain wilting.

A generalised model that explains how growth of *P. solanacearum* in plant xylem vessels causes wilt has not been produced, although groups of non-pathogenic mutants affected in phenotypes ranging from the highly specific (such as altered production of cellulase and *endo*-polygalacturonase) to the less defined (such as induction of the hypersensitive response) have been produced. To construct such a model, the idea of a single factor responsible for bacterial wilt may instead be envisioned as a complex disease aetiology with many significant components.

P. solanacearum produces several extracellular plant-cell-wall-degrading enzymes. These include a cellulase (specifically, endoglucanase) that contributes to pathogenicity (Roberts et al. 1988) and several polygalacturonases (henceforward abbrieviated PG). PG degrades the pectic compounds present in the plant cell wall and middle lamella by a hydrolytic mechanism. There are two types of PG: *endo*-PGs, which cleave the polygalacturonate polymer internally at random, generating rapid loss of viscosity; and *exo*-PGs, which remove one or a few galacturonate residues at a time from the end of the polymer, generating an increase in reducing sugar ends. The action of the purified enzyme results in tissue maceration, formation of pectin gels that may occlude xylem vessels, and release of oligosaccharides that are believed to signal plant defence responses (Ryan 1987). Our research has focused on the role of PG in wilt and the regulation of PG gene expression.

*Department of Plant Pathology, University of Wisconsin-Madison, Madison, Wisconsin, 53706, USA.

Recently, we have found that the extracellular *endo*-PG encoded by *pehA*, which predominates when cells multiply in rich culture media, makes only a minor contribution to virulence (Allen et al. 1991). Similar results were obtained by Schell et al. (1988). A positive *trans*-acting regulatory locus, *pehR*, is required for normal PG production. *pehR* appears to act at the transcriptional level (Allen et al. 1991). Since PG production is induced 100-fold when *P. solanacearum* grows in tobacco leaf tissue, *pehR* may be involved in response to a plant signal (Allen et al. 1991). In the present study, we examined the contribution of *exo*-PG to bacterial wilt and further characterised the *pehR* locus using mutagenesis with a transposon-reporter gene construct.

Materials and Methods

Bacterial strains and plasmids

We used *P. solanacearum* wild type strain K60 (race 1, biovar 1) (Kelman 1954), which is pathogenic on tobacco, tomato, and eggplant, and elicits a hypersensitive response on cucumber. *P. solanacearum* was cultured at 28°C on Casamino-acid peptone glucose (CPG) plates containing 0.05% 2,3,5,-triphenyl tetrazolium chloride (TZC medium) (Kelman 1954). For broth culture, bacteria were grown in either CPG broth or Boucher's minimal medium (BMM) (Boucher et al. 1985) supplemented with 0.1% citrate and 0.1% galacturonate as carbon sources. Plasmids and mutant strains are given in Table 1.

DNA manipulations

General molecular genetic procedures were carried out as described by Ausubel et al. (1989). A *pehA* mutant was generated by ligating the blunted-ended streptomycin resistance cassette from pUC8-Ω (Prentki and Krisch 1984) into the blunted *Cla*I site of pPG3, which interrupts the *pehA* structural gene (Allen et al. 1991). The resulting plasmid was electroporated into K60 and marker exchange mutants were selected and confirmed by Southern blot analysis as described by Allen et al. (1991). The resulting streptomycin-resistant PehA-deficient mutant strain was called K60-06.

Mutagenesis and screening

Transposon Tn*5* mutagenesis of strain K60-06 was conducted as described by Xu et al. (1988), using plasmid pSUP2021 as a suicide vector. Kanamycin- and streptomycin-resistant exconjugants were screened for altered pectolytic enzyme production on pectinase-detection plates (Reverchon et al. 1985). Saturation mutagenesis with transposon Tn*3*-gus was conducted as described by Bonas et al. (1989).

Enzyme assays

PG activity was measured in culture supernatants after strains were grown for 96 hours in BMM supplemented with 0.1% galacturonate and 0.1% citrate. Cleared supernatants were concentrated 20-fold in Centricon-30 microconcentrators (Amicon). *Endo*-PG activity was determined viscometrically as described

by Keen et al. (1984). *Exo*-PG activity was measured as reducing sugar ends generated using the method of Nelson (1944). Pectolytic activity was observed in isoelectric focusing gels by the thin-layer substrate overlay method of Reid and Collmer (1985). β-glucuronidase activity produced by the 'gus' (*uidA*) reporter gene was measured fluorimetrically from bacterial sonicates as described by Jefferson (1987). To measure expression of *pehR in planta*, we infused a 10^8 cfu/mL suspension of washed bacteria into tobacco leaves and then sampled β-glucuronidase activity from five homogenised and sonicated 1 cm^2 leaf disks removed at each time point. Leaf disks were removed in parallel, homogenised, and dilution plated to determine the cfu/cm^2 tobacco leaf.

Pathogenicity assay

Three-week-old eggplants (cv. Black Beauty) were injected in the axil of the second true leaf with 50 μL of a 10^7 cfu suspension of bacteria in water. They were rated daily using a 0–4 disease index, where 0 = no wilting, 1 = 1–25% wilted, 2 = 26–50% wilted, 3 = 51–75% wilted, and 4 = 76–100% wilted or dead. For each assay, we used sixteen plants per treatment; assays were repeated at least three times.

In planta growth

Growth of *P. solanacearum* mutants in plant tissue was determined after infiltrating tobacco leaves with bacterial suspensions, as described by Sequeira and Hill (1974).

Results and Discussion

P. solanacearum produces at least three extracellular polygalacturonases

When concentrated K60 culture supernatants are separated on isoelectric focusing gels, substrate overlays reveal three bands of pectolytic activity at pIs 9.2, 7.2, and 4.9 (data not shown). The pI of 9.2 corresponds to the 56 kd *endo*-PG encoded by *pehA* (Allen et al. 1991; Schell et al. 1988); the other two PGs were named PehB (pI = 7.2) and PehC (pI = 4.9).

PehB and PehC are *exo*-polygalacturonases

Concentrated culture supernatants from strain K60-06, which carries an inactivating insertion in the *pehA* locus, did not contain the pI 9.2 *pehA endo*-PG but still contained the pI 7.2 and 4.9 PehB and PehC PG activities as determined by the isoelectric focusing gel overlay technique. These supernatants were assayed for *endo*- and *exo*-PG activity. No *endo*-PG activity was detected, but the strain produced wild type levels of *exo*-PG activity (Table 2). This result suggests strongly that PehB and PehC are *exo*-PGs.

Table 2. Effect of *pehR* and *pehA* mutations on polygalacturonase production.

[b] nd, none detected.

Obtaining *exo*-polygalacturonase mutants

Production of PehA by the wild type strain masks *exo*-PG production on pectinase detection plates, so we used a *pehA* mutant strain to screen for *exo*-PG mutants. Double mutants affected in production of PehA and either PehB or PehC were generated by subjecting strain K60-06 (*pehA*$^-$) to transposon Tn*5* mutagenesis and screening for reduced PG production on pectinase plates. Two mutants, K7-06 and K14-06 (affected in production of PehB and PehC, respectively), were identified. Cloned Tn*5*-containing fragments from each mutant were marker-exchanged into wild type strain K60 to generate single *exo*-PG mutants.

Polygalacturonase mutant strains grow normally in plant tissue

Bacterial strains were infused into tobacco leaves, which were sampled and dilution-plated over time to generate *in planta* growth curves. Growth of mutants K60-06 (*pehA*), K7-06 (*pehA, pehB*), K14-06 (*pehA, pehC*), and K71 (*pehR*) in tobacco leaves was indistinguishable from wild type strain K60. An *hrp* mutant strain, KD1506, which was included as a control, did not grow in tobacco leaves. Although leaf intercellular space is not the normal route of infection for *P. solanacearum*, this result does indicate that these mutants do not have the kind of fundamental inability to multiply in plant tissue that characterises *hrp* mutants. We cannot conclude, however, that PG is not required for growth *in planta* since all these mutants still produce some PG activity. All strains tested (incuding the *hrp* mutant) exhibited wild type growth in CPG broth.

Exo-polygalacturonase mutants are severely affected in virulence

To determine the effects of these mutations on virulence, eggplants were inoculated with each of the single mutants (*pehA*, *pehB*, and *pehC*) and with two double mutants (*pehA/pehB* and *pehA/pehC*). The results suggest that *PehB* and *PehC* make a more significant contribution to virulence than *PehA* (Fig. 1). Double mutants lacking *PehA* and either *PehB* or *PehC* were less virulent than the *exo*-PG mutants alone. This was an unexpected result since purified *endo*-PG can macerate plant tissue more effectively than *exo*-PG and is usually considered to be more important for virulence in other plant pathogens. Although generalised tissue disintegration is common in the last stages of bacterial wilt, it is not characteristic of the early and middle periods of disease development. These data suggest that *exo*-PG may play a more subtle role in the disease. Are the pectic oligomers released by enzyme activity inducing expression of other bacterial virulence genes? Do these oligomers induce expression of plant genes that contribute to symptom development? Are *exo*-PGs important in early stages of disease development when pectin degradation may help bacteria enter plant roots or move across xylem vessel pit membranes to invade new vascular tissue? To test these hypotheses, we must construct a mutant strain unable to produce any *exo*-PG activity, as well as a completely PG-negative strain. Further, such strains could be used to determine conclusively whether PG production contributes to virulence or is absolutely required for pathogenicity in *P. solanacearum*.

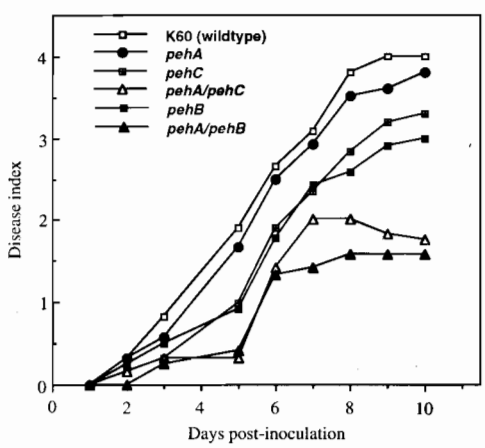

Fig. 1. Virulence on 21-day-old eggplants of various *P. solanacearum* mutants affected in polygalacturonase production. Fifty microlitres of a bacterial suspension was injected into the axil of the second true leaf; plants were rated daily on a disease index from 0–4. For each virulence assay, 16 plants were inoculated with each strain; each point is the mean of 16 plants. The experiment was replicated three times; a representative experiment is shown.

Saturation mutagenesis of the *pehR* region

To better charcterise the positive regulator of PG production, we used transposon Tn*3*-gus, which carries a promoterless β-glucuronidase reporter gene, to saturate the 4.5 kb *Eco*RI fragment containing the previously-identified *pehR* region (Allen et al. 1991). Twenty-four separate transposon insertions were selected for further study (Fig. 2). Curiously, although we analysed more than 200 mutants, we did not obtain any carrying the transposon insertion in the opposite orientation from the direction of transcription. We know of no explanation for this phenomenon. Each of the 24 insertions was marker-exchanged into the wild type strain to generate a population of *pehR*:reporter gene chromosomal mutants.

pehR mutants are substantially affected in virulence

Eggplants inoculated with *pehR* mutant strain K71 developed fewer symptoms at a slower rate than plants inoculated with either wild type strain K60 or the PehA *endo*-PG mutant K60-06 (Fig. 3). Similar results were obtained with four other *pehR* mutants. Many plants exhibited a low level of wilting which they eventually outgrew; a few showed no symptoms whatsoever. No such 'escapes', or symptomless plants, were observed when plants were inoculated with the wild type strain. The reduction in virulence of *pehR* mutants is similar to that observed for the *pehA/pehB* double mutant discussed above.

The *pehR* locus affects production of *exo*-PG and *endo*-PG differently

All *pehR* mutants tested produced very little *endo*-PG activity, ranging from 5–10% of wildtype levels, depending on the region of the transposon insertion. However, all mutants tested still produced about 50% of wild type levels of *exo*-PG activity (Table 2). This reduction in *exo*-PG activity could result from lower expression of both *pehB* and *pehC*, or could be caused by the complete absence of expression of one isozyme of *exo*-PG. Preliminary data in the form of isoelectric focusing gels from *pehR* mutant culture supernatants suggested that both isozymes are present at lower levels (data not shown). Reporter gene insertions in each *exo*-PG gene are necessary to confirm this result. There was a small but reproducible difference in the level of *endo*-PG produced by the mutants related to the region of transposon insertion (Table 2). Insertions K21 through K47, in the central region of the DNA fragment, produced about half as much *endo*-PG as those in the

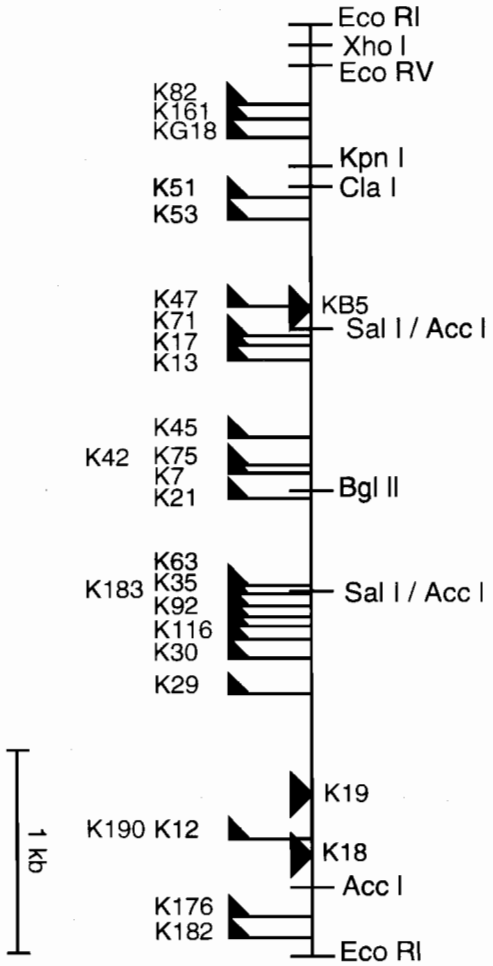

Fig. 2. Physical map of the 4.5 kb *Eco*RI fragment from pKH19. Triangles represent insertions of transposon Tn*5*; flags represent insertions of transposon Tn*3*-gus. The direction of transcription (as determined by reporter gene expression) is indicated by the arrow. No Tn*3*-gus insertions were obtained in the opposite orientation; all insertions affect polygalacturonase activity levels.

outer regions. 'Complementation' studies with *trans*-merodiploids and DNA sequencing results supported the division of the locus into these three apparent units (C. Allen and L. Sequeira, unpublished data).

The *pehR* locus probably extends beyond the 4.5 kb *Eco*RI fragment of pKH19

No strains carrying insertions in the 4.5 kb *Eco*RI fragment produced normal levels of PG; even insertions at the extreme ends of the fragment (K82 and K182) reduced PG production. Furthermore, pKH19, present *in trans*, was unable to restore wild type levels of *endo*-PG expression to any *pehR* mutant, although it did increase *endo*-PG expression and restore wild type *exo*-PG production (Table 2). These results suggest that the region of DNA required for normal PG production is larger than the 4.5 kb fragment previously described.

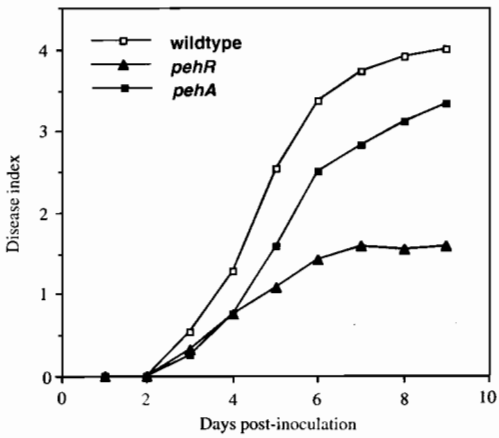

Fig. 3. Virulence on 21-day-old eggplants of *P. solanacearum* mutants affected in *pehR* or *pehA* (pI 9.2 *endo*-polygalacturonase). (See legend to Fig. 1.)

The *pehR* locus is not autoregulated

Several regulatory loci in plant-associated bacteria [see, e.g. Schlaman et al., (1992) and Winans (1992)] have been shown to be autoregulated: that is, the protein product of the regulatory gene can repress its own transcription either directly or indirectly. To determine if *pehR* regulates itself, we transformed three different *pehR*::Tn*3*-gus chromosomal mutants with plasmid pKH19, containing the 4.5 kb *Eco*RI fragment, and the vector alone, pLAFR3. If the *pehR* locus were autoregulated, we would expect to see a decrease in expression of *pehR*-gus fusions in the presence of multiple copies of pKH19. However, β-glucuronidase expression in these strains was essentially unaffected by the presence of these plasmids (Table 3). This result is consistent with the hypothesis that genes for several virulence components are controlled by a global regulatory cascade (M.Schell, pers. comm.). Nevertheless, this conclusion must be preliminary since we suspect pKH19 does not contain the complete *pehR* locus (see earlier), so it is still possible that the region responsible for autoregulation is not present on this plasmid.

Table 3. Effect of multiple copies of pKH19 on expression of *pehR*.

Strain (plasmid)	*gus* activity[a] (% parent mutant)
K35	100

K71 (pLAFR3)	101
K7	100
K7 (pKH19)	93
K7 (pLAFR3)	110

[a]Results given here are the means of three experiments

Expression of the *pehR* locus is increased in minimal medium and in plant tissue

Although β-glucuronidase activity was barely detectable when *pehR*::Tn*3*-gus mutant strains were grown in rich culture medium, activity levels increased about five-fold when bacteria grew in minimal medium supplemented with citrate and galacturonic acid and ten-fold when they grew in tobacco leaves (Fig. 4).

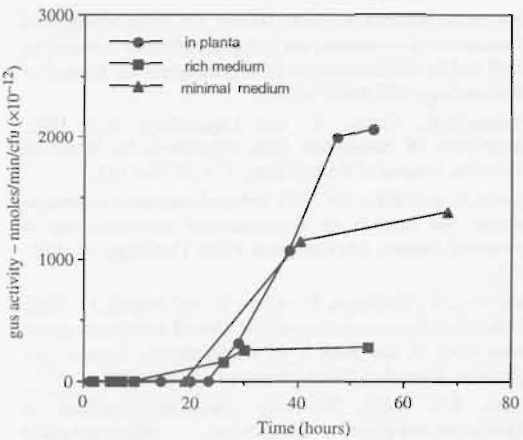

Fig. 4. Expression of *pehR*::Tn*3*-gus fusions in bacteria grown under different conditions. Bacteria grown in CPG (rich medium) or Boucher's Minimal Medium supplemented with 0.1% each citrate and galacturonate (minimal medium) were either quantified by dilution plating or sonicated. Bacteria grown in tobacco leaf tissue were freed from leaf disks by homogenisation and then dilution plated or sonicated. The sonicates were assayed for β-glucuronidase activity fluorimetrically as described in the text. β-glucuronidase activity was normalised to activity produced per cfu.

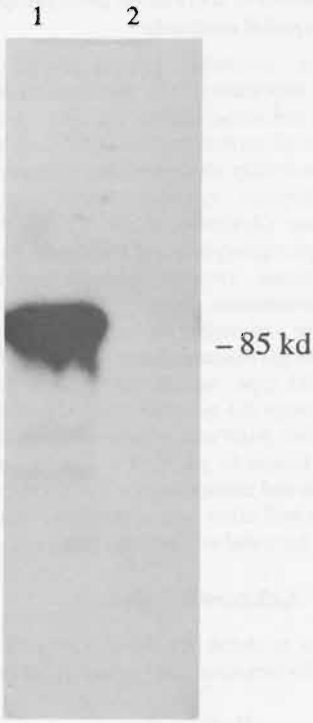

Fig. 5. Reduced in vitro phosphorylation of an 85 kd membrane tyrosine phosphoprotein in a *pehR* mutant strain. Purified membrane proteins (see Atkinson et al., 1992) were incubated with [γ-32P]ATP and proteins were resolved by electrophoresis on a 9% SDS-polyacrylamide gel and autoradiographed. Lane 1, wild type strain K60; Lane 2, *pehR* mutant strain K18.

These increases in *pehR* expression paralleled the apparent induction of PG activity described previously. Total PG activity increased about ten-fold when bacteria grew in minimal rather than rich medium; a 100-fold increase was observed when bacteria grew in tobacco leaves (Allen et al. 1991). We hypothesise that two phenomena contribute to this result: catabolite repression of both PG production and *pehR* expression in the presence of rich media, and induction of these activities in response to a signal present in plant tissue. Preliminary results suggested that the rich medium component responsible for catabolite repression is glutamine (Lewosz et al. 1990). The putative plant signal remains unknown. It is striking that expression of the PG structural genes and their regulatory element appear to be linked; this provides further support for the existence of an 'upstream' regulator controlling expression of *pehR*, which in turn activates expression of *pehA*, *pehB*, and *pehC*.

Phosphorylation of a tyrosine phosphoprotein is reduced in *pehR* mutants

In prokaryotes, reversible protein phosphorylation often plays an important role in transduction of signals within the cell and across the cell wall (as, for example, in response to an environmental condition) (Winans 1992). We previously described the existence of an unusual prokaryotic tyrosine kinase activity in *P. solanacearum* (Atkinson et al. 1992). We have observed that phosphorylation of the kinase's target, an 85 kd membrane tyrosine phosphoprotein, was reduced in membranes from *pehR* mutant strains (Fig. 5). Since phosphorylation in the mutant membranes was not entirely absent but ranged from 0% to 40% of wild type, we do not believe that *pehR* mutations interrupt the tyrosine phosphoprotein structural gene. Rather, *pehR* may regulate expression of this protein or its kinase in addition to the PG structural genes. Isolation and mutagenesis of the phosphoprotein structural gene will allow us to determine what role, if any, it plays in bacterial wilt pathogenesis.

Acknowledgments

We would like to thank Jim Bina, Doug Cook, and Jerzy Lewosz for technical help and useful discussions.

One Specific DNA Piece in *Pseudomonas solanacearum* Affecting *Arachis hypogaea*

J. Feng, M. Zhang, X. Bai, B. Han, T. Liu, M. Fan, J. Tang, and Q. Ma*

Abstract

We previously reported that a 12.8 kb DNA fragment (in plasmid pGX1252) of *Pseudomonas solanacearum* strain T2005 (isolated from *Arachis hypogaea*) could extend the host range of a nonpathogenic strain T2003 to *A. hypogaea*. The genomic DNAs of 21 *P. solanacearum* strains, representing strains isolated from nine hosts in different places, were digested with *Eco*RI, or *Bam*HI/*Eco*RI and probed with radioactively labeled pGX1252. It turned out that all these *P. solanacearum* strains carried DNA sequences homologous to this 12.8 kb DNA but showing different RFLP patterns, with which the 21 strains were classified into seven groups. It seemed that all 16 pathogenic strains to *A. hypogaea* had the 1.9 kb *Bam*HI/*Eco*RI fragment on the right end part of pGX1252, but the five nonpathogenic (to *A. hypogaea*) strains had homologous fragments of different sizes. The 1.9 kb DNA alone could not extend the host range of T2003. More left-flanking sequences were needed for this function. The major homologous fragment of pGX1252 in T2003 was cloned in pGX1415. pGX1415 and pGX1252 were different not only in restriction sites but also in the ability to render T2003 pathogenic to *A. hypogaea*. No homologous sequences of pGX1252 were found in *Rhizobium* sp. *vigna* (*Arachis*), *Pseudomonas maculicola*, *Pseudomonas coronafaciens*, *Pseudomonas fluorescens*, *Xanthomonas campestris* pv. *campestris*, *Xanthomonas oryzae* pv. *oryzae*, *Corynebacterium sepedonicum*, *Erwinia carotovora* subsp. *carotovora* in our conditions.

MUCH work has shown that dozens of bacterial genes are involved in the interaction between bacteria and their host plants. Among these genes, some are essential to confer what has been called the 'basic compatibility' of the bacterium with its plant partner, some determine the host range of a bacterium and yet others may modulate certain stages in interaction between the bacterium and its host plant (Daniels et al. 1988; Ellingboe 1981; Keen and Staskawicz 1988; Long 1989). *Pseudomonas solanacearum* E.F. Smith can cause wilt in many economically important crops such as *Solanum tuberosum* L., *Nicotiana tabacum* L., *Lycopersicon esculentum* Mill, *Arachis hypogaea* L., *Capsicum annuum* L. and *Musa nana* Lour. throughout the world (Buddenhagen and Kelman 1964). The very extensive host range of *P. solanacearum* includes several hundred species representing 44 families of plants, and many newly recognised hosts (Hayward 1991). For some *P. solanacearum* strains the host range is narrow, but with others it is wide.

Molecular analysis of *P. solanacearum* has demonstrated that factors acting in both negative and positive ways may function in determining its host range (Carney and Denny 1990, 1991; Ma et al. 1988). Carney and Denny (1990) identified an *avr*A gene from *P. solanacearum* strain AW1, nonpathogenic to *N. tabacum*, which restricted the host range of a *N. tabacum*-pathogenic strain NC252 to exclude *N. tabacum*. Recently they showed that a 4.2 kb *Eco*RI/*Bam*HI fragment of AW1, where *avr*A was located, rendered another *N. tabacum*-pathogenic strain K601 nonpathogenic to *N. tabacum* (Carney and Denny 1991). However, unlike *avr* genes acting at the race-cultivar level of other phytopathogenic bacteria, the derivative mutant strain of AW1, in which the avirulence gene had been inactivated by the insertion of Tn*5*, did not become pathogenic on *N. tabacum*, suggesting that

*Laboratory of Molecular Genetics, Guangxi Agricultural College, Nanning, Guangxi, 530005, People's Republic of China.

AW1 lacks positive-acting host range genes that are required for pathogenicity on *N. tabacum* (Carney and Denny 1990, 1991).

We previously described a 12.8 kb *Eco*RI DNA fragment, carried in plasmid pGX1252, from a *P. solanacearum* strain T2005, which could extend the host range of strain T2003 from *S. tuberosum* (nonpathogenic to *A. hypogaea*) to include *A. hypogaea* (Ma et al. 1988). Therefore, it was of interest to know if DNA sequences homologous to this 12.8 kb DNA were present in other *P. solanacearum* strains isolated from different host plants in different places, in *Rhizobium* sp. *vigna* (*Arachis*) which specifically nodulate *A. hypogaea* and plants of its cross-inoculation group, and also in other common phytopathogenic bacteria. Here we present data to show that this 12.8 kb DNA sequence is present and shows RFLP pattern in all the 21 *P. solanacearum* strains tested, in *Pseudomonas syzygii* and blood disease bacterium of banana, but not in other common phytopathogenic bacteria. It seems that all the 16 *A. hypogaea*-pathogenic strains share the 1.9 kb *Bam*HI/*Eco*RI fragment on the right end part of pGX1252.

Restriction Map of pGX1252 and Its Two Deletion Mutants

A restriction map of pGX1252 and its two subclones, pGX1401 and pGX1402 is shown in Figure 1. There are no *Hind*III and *Hpa*I sites along the 12.8 kb

[a] Host plant and geographical origin of each strain are given according to previously published information or according to personal information from the source.

[b] The pathogenicity of all these strains on *A. hypogaea* is given according to the plant tests carried out in our laboratory using the stem-injection method: – means nonpathogenic to *A. hypogaea* and + stands for pathogenic to *A. hypogaea*.

[c] Strains that show an identical hybridising pattern with a particular digestion share an independent common RFLP group number. Size of hybridising bands (in kb) in all the digestions is: 1: 9.4, 3.8, 0.6. 2: 12.8. 3: 13.7. 4: 16.5. 5: 16.0, 3.4. A: 13.5, 10.2, 5.6. B: 1.7,8.0, 7.6. C: 9.7, 11.9. D: 11.6, 8.0, 7.6. E: 1.7, 9.9, 7.6. F: 1.7, 11.6, 7.6.G: 11.2, 7.3. a: 7.0, 3.5, 2.2. b: 1.7, 8.0, 1.9. c: 9.7, 1.9. d: 1.9, 8.0, 1.9. e: 1.7, 9.9, 1.9. f: 1.7, 11.6, 1.9. g: 9.5, 6.6, 1.8. The fragments read from left to right in B, C, D, E, F, b, c, d, e and f are homologous to the 1.7 kb, 8.0 kb and 1.9 kb DNA fragments of pGX1252 (*Bam*HI/*Eco*RI digestion), respectively.

[d] ?ambiguous or unknown.

sequences. The presence of pGX1252 in twenty-one *P. solanacearum* strains (Table 1) representing strains isolated in different places from *S. tuberosum*, *C. annuum*, *L. esculentum*, *Boehmeria nivea* Gaud., *Zingiber officinale* Rosc., *A. hypogaea*, *N. tabacum*, *Morus alba* L. and *Syzygium aromaticum* Merr. et Perry, were investigated for homology with pGX1252. The pathogenicity of all these strains on *A. hypogaea* was retested and confirmed by a stem-injection method previously described (Ma et al. 1988) (Table 1). Extraction of genomic DNA, digestion with restriction enzyme, gel electrophoresis, Southern transfer, and separation of DNA fragments from low-melting-point agarose gel were conducted according to the standard procedures (Hopwood et al. 1985; Ma et al. 1988; Maniatis et al. 1982;). Radioactively-labeled DNA was prepared by nick-translation (Rigby et al. 1977). Hybridisation was carried out in 3 × saline sodium citrate (SSC), 5 × Denhardt's solution, and 100 μg/mL of denatured salmon sperm DNA at 68°C for 16–20 hours. The filters were washed in a solution of 0.2 × SSC, 0.2% SDS at 68°C for 1 hour then exposed to Fuji X-ray film at –70°C in the presence of intensifying screens.

The *Eco*RI, *Bam*HI or *Bam*HI/*Eco*RI digested genomic blots of 21 *P. solanacearum* strains were hybridised with the 12.8 kb DNA of pGX1252. It turned out that variable homologous sequences of this 12.8 kb DNA were present in all the strains tested (Figs. 2–4 and Table 1). Digestion with *Bam*HI or *Bam*HI/*Eco*RI was more effective than with *Eco*RI to produce RFLP. In one sort of digestion, strains sharing identical hybridising band(s) were given an independent common RFLP group number. Thus, these strains might be classified into seven (*Bam*HI/*Eco*RI digestion) clearly different RFLP groups (Table 1). Strains in groups *b*, *c*, *d*, *e*, and *f* were pathogenic to *A. hypogaea* and had a 1.9 kb homologous DNA fragment of pGX1252 in the genomes, but the nonpathogenic (to *A. hypogaea*) strains in group *a* and *g* did not. This 1.9 kb DNA fragment was confirmed to correspond to the 1.9 kb *Bam*HI/*Eco*RI fragment on the right end part of pGX1252 (Fig. 1) by probing *Bam*HI/*Eco*RI digested genomic DNAs of *A. hypogaea*–pathogenic strains with the plasmid of pGX1402 (Fig. 1, Fig. 5 lane B-N). S710 and S925 belonging to group *c* and *d*, respectively, did not give the 1.7 kb hybridising band corresponding to the left 1.7 kb *Bam*HI fragment of pGX1252 as strains in group b, e and f did in *Bam*HI or *Bam*HI/*Eco*RI digested hybridisations. Strains from each group of *b*, *c*, *d*, *e* and *f* carried DNA fragments of different size homologous to the internal 8.0 kb *Bam*HI fragment of pGX1252.

These findings might indicate that the DNA sequences on the right end part of pGX1252 were more conserved than those at the left part of pGX1252 and therefore that the 1.9 kb *Bam*HI/*Eco*RI DNA fragment which was specific to *A. hypogaea*-pathogenic strains was more important in determining the host range of these strains to include *A. hypogaea*. However, when pGX1402 (Fig. 1) was introduced into a nonpathogenic derivative strain of T2003, the resultant transconjugant could not wilt *A. hypogaea* seedlings. Nevertheless, the deletion mutant pGX1401 (Fig. 1) retained the ability of pGX1252 to extend the host range of T2003 to include *A. hypogaea*. This demonstrated that the 1.9 kb DNA alone was not enough to render the transconjugant of T2003 pathogenic to *A. hypogaea* and more left-flanking sequences were needed to do so.

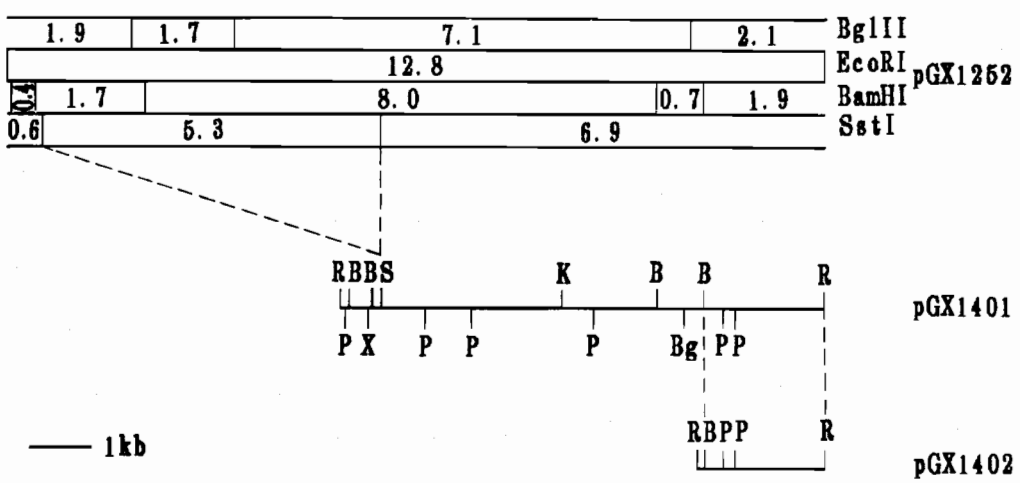

Fig. 1. Restriction map of the 12.8 kb DNA of strain T2005 cloned in the *Eco*RI sites of pLAFRI and its deletion mutants of pGX1401 and pGX1402 (also in pLAFRI). The numbers are fragment sizes in kilobases. Symbols are: E, *Eco*RI; B, *Bam*HI; Bg, *Bgl*II; S, *Sst*I; P, *Pst*I; K, *Kpn*I; X, *Xho*I.

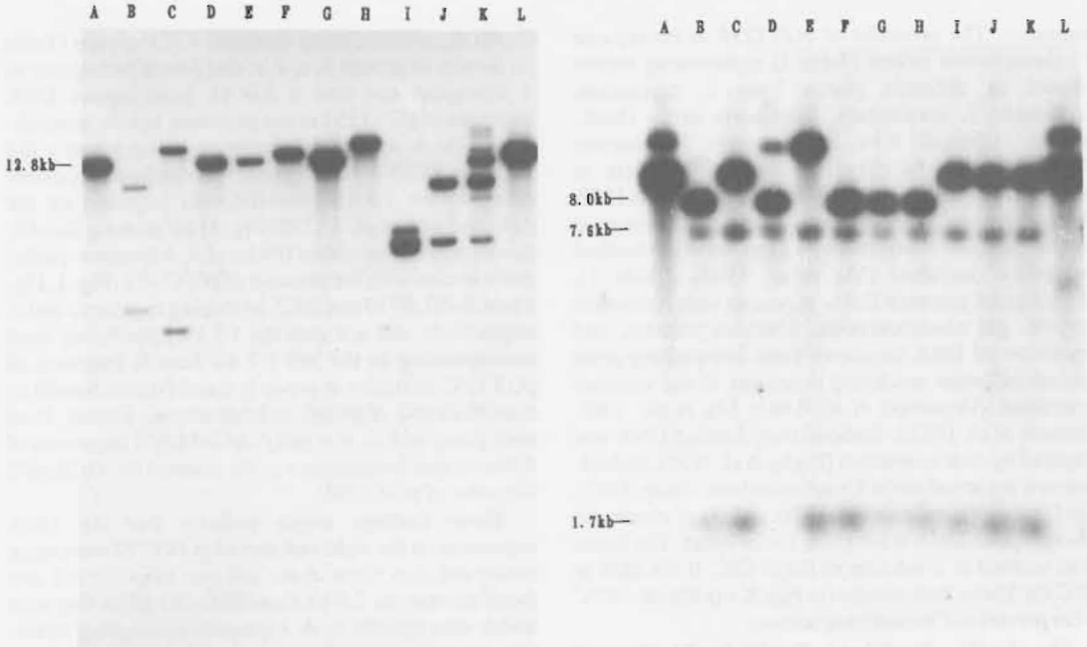

Fig. 2. (left) Hybridisation patterns of *Eco*RI-digested total genomic DNA from strains of *Pseudomonas solanacearum*, *Pseudomonas syzygii* and blood disease bacterium of *M. nana* with probe pGX1252. From lane A to H are *Pseudomonas solanacearum* strains T2005, T2003, B9043, S710, T305, S825, S925, S729. From lane I to K are *Pseudomonas syzygii* strains S442, S444, T328. Lane L is *M. nana* blood disease bacterium strain T394.

Fig. 3. (right) Hybridisation patterns of *Bam*HI-digested genomic blots of *Pseudomonas solanacearum* strains with probe pGX1252. Strains included are: A, S710; B, T305; C, S825; D, S925; E, S729; F, PPs; G, TbPs; H, MPs; I, GPs1; J, GPs2; K, TPs; L, T2003.

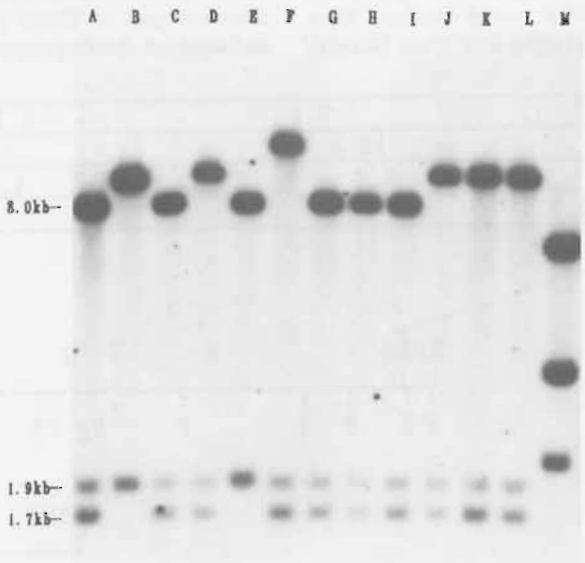

Fig. 4 Southern blot analysis by probe pGX1252 of double digested (*Bam*HI/*Eco*RI) genomic DNA of *Pseudomonas solanacearum* strains. A, T2005; B, S710; C, T305; D, S825; E, S925; F, S729; G, PPs; H, TbPs; I, MPs; J, GPs1; K, GPs2; L, TPs; M, T2003.

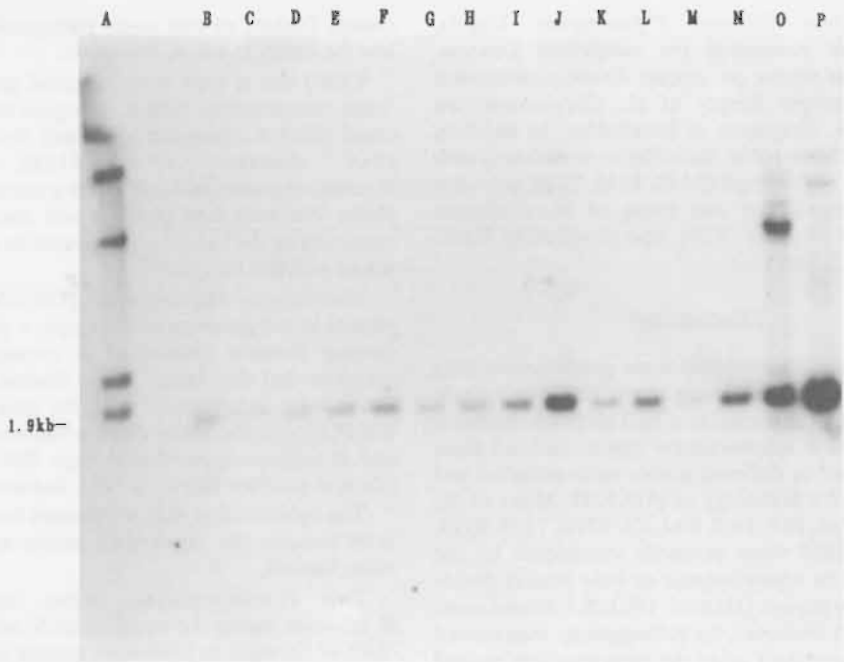

Fig. 5 Presence of the 1.9 kb *Bam*HI/*Eco*RI fragment at the right end part of pGX1252 in the *A. hypogaea* - pathogenic *Pseudomonas solanacearum* strains. The total genomic DNA was double-digested with *Bam*HI and *Eco*RI and probed with radioactively labeled mini-prepared plasmid DNA of pGX1402. A, DNA (*Hind*III); B, T2005; C, PPs; D, TbPs; E, MPs; F, GPs1; G, GPs2; H, TPs; I, T305; J, Po1; K, Pe1; L, Tm2; M, Bn1; N, Z1; O, SW325; P, SW326. SW325 and SW326 were field isolates from *N. tabacum* plant. The weak larger hybridising bands of some strains may come from partial digestion of total DNA or hybridising with the contaminated genomic DNA of *E.coli* in the probe.

Homology of pGX1252 with the Non-pathogenic *P. solanacearum* Strains

Interestingly, when the *Eco*RI digested genomic DNAs of T2003, Po42, Po44, Po46 were probed with pGX1252, they showed identical hybridising bands of 9.4 kb, 3.8 kb and 0.6 kb, but only one band of 9.4 kb appeared with probe pGX1401. The previously prepared genomic library of T2003 (Ma et al. 1988) was in situ hybridised with the 12.8 kb DNA of pGX1252. Seven positive clones were isolated. All these clones contained the 9.4 kb *Eco*RI fragment but not the 3.8 kb and 0.6 kb *Eco*RI fragments. This 9.4 kb DNA piece was subsequently subcloned in plasmid pGX1415. The insert of pGX1415 was in single-copy in the genome of T2003 although it was scattered in seven clones in the gene library. The restriction sites of *Bam*HI, *Pst*I and *Bgl*II along the DNA stretches of pGX1252 and pGX1415 were different. Complementation tests showed that the 9.4 kb DNA sequences in the genome of T2003 were inactivated in controlling T2003 to affect *A. hypogaea*.

Investigation of Homology of pGX1252 in Other Bacterial Strains

One of the features of the *Rhizobium*–legume symbiosis is that it is specific, individual legume hosts being nodulated only by particular strains or species of *Rhizobium* (Gotz et al. 1985). *R.* sp. *vigna* (*Arachis*) can form nodules specifically on *A. hypogaea* and plants of its cross-inoculation group. The 12.8 kb DNA sequences in the genome of *P. solanacearum* strain T2005 are mainly responsible for determining the hosts of this strain, including *A. hypogaea*. Did any homologies exist between pGX1252 and the *hsn* genes in *R.* sp.*vigna* (*Arachis*)? To answer this question, the genomes of six *R.* sp. *vigna* (*Arachis*) strains were probed with the 12.8 kb DNA. As a result, no DNA bands were found to light up even at low stringency conditions (6 × SSC in hybridisation solution, washing in a solution of 2 × SSC, 0.2% SDS, 1 hour room temperature). No homology of pGX1252 was found with the following phytopathogenic bacteria in our conditions (normal stringency): *P. maculicola* Stevens,

P. coronafaciens Stevens, *P. fluorescens* Migula, *Xanthomonas campestris* pv. *campestris* Dowson, *Xanthomonas oryzae* pv. *oryzae*, *Erwinia carotovora* subsp. *carotovora* Bergey et al., *Corynebacterium sepedonicum*. Skaptason et Burkholder. In addition, with pGX1252 as probe, homologies were found with three strains of *P. syzygii* (S442, S444, T328, provided by Eden-Green), and one strain of blood disease bacterium of *M. nana* (T394, also provided by Eden-Green) (Fig. 2, lane I-L).

Discussion

We previously reported that some genes determining the hosts of *P. solanacearum* strain T2005 to include *A. hypogaea* were carried in a 12.8 kb DNA fragment. A further 20 *P. solanacearum* strains isolated from different hosts in different places were collected and investigated for homology of pGX1252. Many of the strains, i.e. Po1, Pe1, Tm2, Bn1, Z1, S710, T305, S925, S729 and S825 were primarily considered by the providers to be nonpathogenic or only weakly pathogenic to *A. hypogaea* (He et al. 1983; S.J. Eden-Green, pers. comm.). However, the pathogenicity tests carried out in our laboratory using the stem-injection method described by Ma et al. (1988) revealed that these 10 strains could cause typical wilting disease on *A. hypogaea* seedlings. This was confirmed by the hybridisation experiments using pGX1252 as probe. The hybridising patterns of the *A. hypogaea*–pathogenic strains (according to pathogenicity tests in our laboratory) were clearly distinct from those of nonpathogenic strains. It seemed that all the pathogenic strains had the 1.9 kb *Bam*HI/*Eco*RI fragment located on the right end part of pGX1252 but the nonpathogenic strains had not. This 1.9 kb DNA fragment alone could not extend the host range of T2003 to include *A. hypogaea*. More left-flanking sequences were needed for this function. Results of the homologies of the 0.7 kb *Bam*HI fragment adjacent to the left of the 1.9 kb *Bam*HI/*Eco*RI fragment and the 0.4 kb *Bam*HI fragment on the left border of pGX1252 (Fig.1) varied and thus were not considered because even for the original strain T2005 these two small bands could sometimes be detected and sometimes not.

pGX1415 of T2003, homologous to pGX1401 or pGX1252 of T2005, did not have the function of pGX1252 or pGX1401 in determining the host range of *P. solanacearum* strain T2005 to include *A. hypogaea*. It might be that the DNA sequences of pGX1415 in T2003 were derived from those of pGX1252 in T2005 because of evolution or mutation. The data presented here indicates that DNA sequences on the left part of pGX1252 in the 16 pathogenic strains were more changeable. It is possible that the bases on the right part of or whole pGX1252 will change further, so that some pathogenic strains will lose the ability to wilt *A. hypogaea*.

T2003 has at least some essential genes encoding 'basic compatibility' with *A. hypogaea* because T2003 could affect *A. hypogaea* by simply obtaining T2005 DNA sequences of pGX1252. Any one *P. solanacearum* strain can affect a certain number of plants. For each host plant, is any specific factor(s) employed by the bacterium to control its specific interaction with that host plant?

Homologous sequences of pGX1252 were also present in the genomes of *P. syzygii*, a plant pathogen causing Sumatra disease of *S. aromaticum* and a pseudomonad that causes blood disease on *M. nana*. These were in agreement with the previous findings that *P. syzygii*, the blood disease bacterium of banana and *P. solanacearum* shared high DNA similarities (Cook et al. 1989; Hayward 1991; Roberts et al. 1990).

The hybridisation data we present here are preliminary because the number of strains employed was rather limited.

Two *P. solanacearum* strains isolated from *N. tabacum* during the outbreak of *N. tabacum* wilt in Yulin of Guangxi in 1990 were probed with pGX1402 and gave the 1.9 kb *Bam*HI/*Eco*RI hybridising band (Fig. 5, lane O and P). In subsequent pathogenicity tests, they wilted *A. hypogaea* seedlings. We are now sequencing the 1.9 kb *Bam*HI/*Eco*RI fragment. Based on the sequence information, suitable primers may be designed to specifically determine with PCR technique if certain *P. solanacearum* strains have the potential to affect *A. hypogaea*. PCR may also be used to detect the viability of *P. solanacearum* in field collected seed and thus be useful for quarantine activities. The expression and regulation of this gene(s) will also be studied.

Acknowledgments

We thank Li-yuan He, S.J. Eden-Green, Jian-hua Zhang, and He-yuan Cheng for providing us with *P. solanacearum* and other bacterial strains. This work was supported by Rockefeller Foundation Fellowship RF84009 No.7 to Qing-sheng Ma and by grants from the Chinese Academy of Science and Guangxi Science and Technology Committee, China.

Regulation of virulence in *Pseudomonas solanacearum*

T.P. Denny, S.M. Brumbley, B.F. Carney, S.J. Clough, and M.A. Schell*

Abstract

A complex regulatory network controls production of some extracellular macromolecules that *Pseudomonas solanacearum* strain AW1 needs for full virulence on tomato. Expression of genes for extracellular polysaccharide (EPS) and other virulence factors is coordinately controlled by *phcA*, since inactivation of this gene results in a pleiotropic change called phenotype conversion (PC). *PhcA* is likely to be a *trans*-acting DNA-binding protein because it has strong similarity at the amino acid level to the LysR family of transcriptional activators. At least three different insertions were detected within *phcA* after spontaneous PC, suggesting that random inactivation of this gene is responsible for this phenomenon. Another locus, *phcB*, is necessary for production by wild-type *P. solanacearum* strains of a volatile inducer compound that appears to be required for full activity of *PhcA*. Cell density, and thus levels of the endogenous inducer, appear to mediate expression of a *PhcA*-regulated *eps*::*lacZ* fusion. Expression of *eps* genes also depends on three additional loci (*xpsR*, *vsrA*, and *vsrB*), two of which encode membrane-associated proteins and thus may serve as environmental sensors. These findings suggest that current concepts regarding the physiology, ecology, and possible strategies for controlling *P. solanacearum* should be re-evaluated.

In the last ten years there has been substantial progress in elucidating the genetic and biochemical bases of pathogenesis of *P. solanacearum*. For example, the genes encoding several of the putative virulence factors identified in the 1950s were cloned and subsequently inactivated to test their contribution to the typical wilt symptoms. It is now clear that, *in planta*, the extracellular polysaccharide (EPS) is the primary virulence factor (Denny and Baek 1991; Kao and Sequeira 1992), whereas the extracellular endoglucanase (EG) and *endo*-polygalacturonase (*endo*-PG) enzymes, which may act on plant cell walls, are relatively minor virulence factors (Denny et al. 1990). In contrast to these factors that enhance virulence but are dispensable, the *hrp* genes are essential for pathogenesis on compatible hosts and the hypersensitive response on incompatible hosts (Boucher et al. 1992). Unlike virulence mutants, strains with one or more *hrp* genes inactivated grow very poorly *in planta* (Macol 1989; Trigalet and Demery 1986) and cause no disease symptoms.

Despite these and other significant advances, our understanding of the pathogenic processes of *P. solanacearum* is still incomplete. Not all of the putative virulence factors have been examined (Denny and Schell 1992) and even those mentioned above have not been tested for their role in other aspects of pathogenesis or saprophytic survival. Even less is known about regulation of genes encoding pathogenesis-specific molecules. This paper will discuss some of our recent research on phenotype conversion in *P. solanacearum* and the associated regulatory network that controls virulence.

Phenotype Conversion

Nearly four decades ago Kelman (1954) reported that when *P. solanacearum* spontaneously changes from a mucoid to a nonmucoid colony morphology there is a concomitant loss of its capacity to wilt plants. These non-mucoid strains are not *hrp* mutants, because they still grow in planta (Denny and Baek 1991) and cause

*Departments of Plant Pathology and Microbiology, 2105 Plant Science Building, University of Georgia, Athens GA 30602, USA.

disease symptoms such as stunting, stem necrosis, and proliferation of adventitious roots (nodules) (Denny and Baek 1991; Denny et al. 1988; Husain and Kelman 1958). Since additional traits are usually affected simultaneously (Brumbley and Denny 1990; Buddenhagen and Kelman 1964), we now call this phenomenon phenotype conversion (PC) and refer to the resulting mutants as PC types.

PC types are easily recognised on standard agar media supplemented with tetrazolium chloride because they are round, butyrous, and dark red, which is in stark contrast to the irregularly-round, mucoid, pink or white parent colonies. This change in colony type is due to loss of one or more components of the EPS (Husain and Kelman 1958; Orgambide et al. 1991). True PC-type strains also have a coordinate 100-fold reduction in EG activity and are markedly more motile (Brumbley and Denny 1990; Kelman and Hruschka 1973). The decreases in production of EPS and EG are due to reduced transcription of genes that encode these virulence factors and not to mutation or deletion of these genes (Denny and Baek 1991; Huang et al. 1989; Schell et al. 1987). In addition, *endo*-PG activity increases 10-fold and extracellular pectin methylesterase activity decreases about 15-fold (Schell et al. 1993). Polyacrylamide gel electrophoresis (PAGE) of culture supernatants has shown that additional extracellular proteins are altered by PC (Schell 1987; Schell et al. 1993), but their genes and biochemical functions are unknown.

Large numbers of PC types routinely appear when *P. solanacearum* is cultured in broth containing glucose and an organic nitrogen source for 5–7 days without shaking, whereas identical cultures that are shaken do not give rise to PC types (Kelman and Hruschka 1973). In contrast to these results, we recently found an inorganic liquid medium that promotes appearance of PC types in shaken as well as unshaken cultures of strain AW1. This liquid minimal medium (MM) consists of (per litre): 1.75 g K_2HPO_4, 0.75 g KH_2PO_4, 0.14 g Na citrate-$2H_2O$, 26 mg $MgSO_4$-$7H_2O$, and 1.25 g $(NH_4)_2SO_4$; 0.5% (w/v) glucose is added after autoclaving. The Mg^{2+} and sodium citrate in MM synergistically enhance growth of wild type strain AW1. However, AW1-PC, a PC type derivative of AW1, grows even better in MM than does the wild type, and this difference is enhanced by 4MM, which has four times the standard concentrations of all components except glucose (Table 1). A similar effect was observed when MM was supplemented with either NaCl, KCl, or NH_4Cl at a final concentration of 0.1 M (approximately equal to the concentration of 4MM). It was presumably this differential growth rate that resulted in the appearance of 4–16% PC types when cultures of AW1 in 4MM liquid medium were shaken for 4 days (Table 2). By serially transferring cells to fresh medium each day the number of PC types recovered increased markedly (Table 2), probably because the larger number of generations permitted by this schedule 'amplified' the growth advantage of the PC type cells. PC types also arise during prolonged culture on agar plates and in wilted plants (Buddenhagen and Kelman 1964; Brumbley and Denny, unpublished data), which suggests that there may be natural conditions that favour the appearance or multiplication of PC types.

Table 2. Percentage of *P. solanacearum* PC types after four days in MM liquid medium with agitation[a]

Culture conditions[b]	MM concentration		
	4	1	1/4
No transfer	10±6	0.3	0
Three transfers	90±2	50±20	7±0.5

[a]MM media were as described in Table 1. Cultures were started with approximately 1×10^6 wild type cells/mL. After incubation, serial dilutions were made to determine the percent of PC type colonies; values are the mean for two experiments ± range.

[b]Cultures were incubated for 4 days at 30°C and 250 rpm. One set of cultures was transferred to fresh medium at 24 hour intervals; each subculture was started with approx. 1×10^6 cells/mL.

Table 1. Growth of *P. solanacearum* in various MM and BG liquid media with agitation[a]

Strain[b]	Incubation time							
	24 hours				48 hours			
	4MM	MM	1/4MM	1/10BG	4MM	MM	1/4MM	1/10BG
AWl	0.03	0.48	0.32	0.68	0.90	1.55	0.94	0.85
AWl-PC	1.18	1.3	0.68	0.48	>2.0	1.48	0.62	0.74

[a]MM medium contained 4-, 1- or 1/4-times the standard salt concentration (see text). 1/10BG contained 0.1% each of peptone, casamino acids, and yeast extract. All media were supplemented with 0.5% glucose after autoclaving. Cultures were started with approx. 1×10^6 cells/mL, and were incubated at 30°C, 250 rpm. Values are turbidity at 600 nm and are representative of two or more experiments.

[b]AWl is wild type; AWl-PC is a spontaneous PC type derived from AWl..

The Role of *PhcA* in Phenotype Conversion

Our genetic study of PC began with the isolation of a Tn*5*-insertion mutant that mimicked a spontaneous PC type (Denny et al. 1988). The Tn*5*-tagging of a region apparently involved in PC allowed us to isolate a wild-type gene from strain AW1, designated *phcA* (for phenotype conversion), that restores PC types of AW1 to wild type (Brumbley and Denny 1990). Complementation studies and site-directed mutagenesis of 12 other strains of *P. solanacearum* suggested that PC generally results from the loss of *phcA* gene expression or the function of the *phcA* gene product. DNA sequencing of *phcA* and analysis of the deduced amino acid sequence showed that *phcA* is similar to members of the LysR family of transcriptional activators and has a putative helix-turn-helix DNA-binding motif (Brumbley 1992; Brumbley and Denny 1991; Henikoff et al. 1988). The greatest similarity was with *Nah*R, from the NAH7 plasmid in *Pseudomonas putida*. These results suggest that *phcA* is likely to be a *trans*-acting, DNA-binding protein that simultaneously regulates transcription of multiple virulence factors. Preliminary data have shown that *phcA* does bind in vitro to DNA upstream of the *xpsR* regulatory gene (see next section; Carney and Denny, unpublished data).

An analogous allele, designated *phcA1*, was isolated from the spontaneous PC-type strain AW1-PC by using *phcA* as a hybridisation probe (Brumbley et al., unpublished data). Sequence analysis of *phcA1* revealed a two-base insertion near the 3' end, and the resulting frameshift changes the next 24 amino acids and eliminates the last 25 amino acids due to a premature termination of transcription. These changes are apparently sufficient to inactivate *phcA*. Southern blot analysis of genomic DNA from 10 independently isolated PC types of AW1 revealed that only two of the strains had detectable insertions (0.2 and 1.0 kb) in *phcA*, which suggests that spontaneous PC can be the result of more than one type of mutation in *phcA*. Thus, it now seems likely that spontaneous PC is often the result of various, random mutational events within *phcA*.

Regulation of Virulence by a Complex Network

Although the investigation of *phcA* gave us our first indication that *P. solanacearum* can regulate virulence, we have subsequently discovered four additional genes that affect virulence gene expression and hence disease development. One of these loci is *phcB*, which when inactivated in strain AW1-83 gives a phenotype similar to a spontaneous PC type except for several major differences (Brumbley and Denny 1990). First, *phcB* is physically distinct from *phcA*, which remains functional in AW1-83. Second, unlike a true PC type, AW1-83 is reversibly 'induced' to wild type, EPS^+ phenotype when grown in the same Petri dish adjacent to, but not in contact with, a wild-type strain of *P. solanacearum*. We now know that this extracellular complementation is due to production by wild type strains of a moderately volatile, water soluble 'endogenous inducer' (EI) that AW1-83 does not make (Clough and Denny 1990). The EI has not been chemically identified, but several purified compounds, (e.g., methanol and fatty acid methyl esters, but not ethylene), can substitute for the EI (Clough 1991; Clough and Denny 1991). Production of the EI seems to be another trait regulated by *phcA*, because PC-type mutants very weakly induce AW1-83.

Based on this and other observations, we believe that *phcB* is involved in synthesis or modification of an EI that is required along with *phcA* to activate transcription of virulence genes to wild type levels. Thus, *P. solanacearum* may have an extracellular cell–cell signalling system that regulates virulence that is analogous to the to the cell-density dependent bioluminescence in marine *Vibrio* species, which depends in part on the concentration of nonvolatile 'autoinducers' (Meighen 1991). Preliminary results with *P. solanacearum* support this hypothesis, because expression of a *phc*A-regulated *eps*::*lacZ* fusion in a wild-type background was 50-fold less in cells from low density log-phase cultures compared with cells from fully grown log-phase cultures. This type of behaviour means that at low cell density *P. solanacearum* may have a different phenotype than that which is normally seen at high cell density.

A simpler experiment that may demonstrate intercellular signalling required only spreading serial dilutions of wild type *P. solanacearum* on medium (without tetrazolium chloride) to give either 1000, 100, or 10 colonies per plate, and then observing carefully during incubation. As the colonies matured, they appeared first as transparent spots visible only by reflected light, but later became opaque and white; we associate this change in colony morphology of the wild type with EPS production, because colonies of a PC type remain transparent even when mature. Surprisingly, opaque white colonies developed sooner, and had 10-fold more cells per colony, on the plate seeded with 1000 cells than at the lower two densities. Comparable plates that had 10 µL of methanol (i.e., an exogenous inducer) added to the Petri dish lids had opaque white colonies develop sooner at the lower densities than on those plates without methanol. One explanation of these results is that independent colonies act cooperatively to mature more rapidly at high colony density, and that this cooperation may be due to EI since the addition of exogenous inducer compensated for low colony density.

We have found three more nonallelic loci (*vsrA*, *vsrB*, and *xpsR*) that, when inactivated, give mutants that are deficient in EPS production, probably due to a 25-fold reduction in transcription of *eps* genes observed for *lacZ* reporter fusions (Huang et al. unpublished data). Not surprisingly, each of these mutants was markedly reduced in ability to wilt stem-inoculated tomato plants. PAGE analysis of extracellular proteins showed that inactivation of *vsrA*, *vsrB*, or *xpsR* affects production of some of the extracellular proteins that are regulated by *phcA*. Based on these and other data, we propose that these loci encode intermediate virulence regulators working below the global level of *phcA*. In other words, *phcA* appears to be a master switch that probably controls expression of virulence indirectly via these intermediate regulators. In support of this model, we found that *phcA* appears to regulate expression of *xpsR* which, in turn, affects expression of *eps* genes. Other experiments suggest that *xpsR* protein requires *vsrA* to fully activate expression of *eps*. Various analyses show that *vsrA* is a membrane-associated protein which is likely to be an autokinase sensor of the two-component type (Stock et al. 1989). *vsrB* is also membrane-associated, and appears to negatively regulate production of the *endo*-polygalacturonase. Much of our evidence suggests that *vsrA* and *vsrB* respond to environmental signals (e.g., organic nitrogen levels). Therefore, like other pathogenic bacteria (Mekalanos 1992), *P. solanacearum* has a complex regulatory network to control virulence.

Conclusions

It is now clear that virulence of *P. solanacearum* is a trait regulated by a sophisticated, multicomponent network that is sensitive to the environment. Rather than being part of this response system, spontaneous PC types are likely to be just one of the many mutations that occur in a microbial population, and may serve no purpose in natural settings. Instead, it now appears as though *P. solanacearum* can use the *phcA*/EI system to reversibly switch between a low virulence PC-like phenotype and the highly virulent wild type, partly in response to cell density. At the same time, virulence can be modulated by other environmental signals via *vsrA* and *vsrB*. These findings suggest that we should re-evaluate our current concepts of the ecology and physiology of *P. solanacearum* (Hayward 1991). In addition, the finding that virulence of *P. solanacearum* is responsive to its environment, opens a door to a new line of research that may result in novel approaches to controlling bacterial wilt disease.

Hrp Mutants of *Pseudomonas solanacearum* for the Biological Control of Tomato Bacterial Wilt

P. Frey*, P. Prior*, D. Trigalet-Demery†, and A. Trigalet†

Abstract

During the last decade there has been increased interest in the biological control of bacterial wilt caused by *Pseudomonas solanacearum* E.F. Smith. Recent advances in knowledge of the genetic determinants of *P. solanacearum* pathogenicity suggested that a biological control method could be developed using avirulent mutants of *P. solanacearum*.

Three virulent strains (GA2, GA4, and GT4) collected on Guadeloupe (French West Indies) were transformed by insertion of the Ω-Km interposon within the *hrp* gene cluster. The resulting avirulent mutants (GMI 8171, GMI 8172, and GMI 8173, respectively) were assessed in a contained environment on Guadeloupe. Upon root inoculation, these mutants colonised only the lower part of susceptible tomato plants (cv. Floradel), but did not reach the fruits. Moreover, the presence of an avirulent strain in the plant did not affect fruit production. Inoculation of Floradel with GMI 8171, GMI 8172, or GMI 8173 resulted in some protective effect when the plants were subsequently inoculated with the virulent strain GMI 8217. The avirulent mutants were detected in collar tissue at much lower densities (ca. 10^5 cfu/g dry weight) than the virulent strain (ca. 10^{10} cfu/g dry weight). Thus protection did not result from exclusion of the virulent strain. Furthermore, there was evidence that strain GMI 8217 produced in vitro and in planta a bacteriocin that inhibited growth of numerous strains of *P. solanacearum*, including the three avirulent mutants. The results suggest that protection of tomato against bacterial wilt could have been the result of induced plant resistance.

BACTERIAL wilt caused by *Pseudomonas solanacearum* is a serious disease of several agriculturally important plants in tropical, subtropical and warm temperate regions of the world (Hayward 1991). There have been several attempts to control bacterial wilt using antagonistic bacteria (Kempe and Sequeira 1983; Anuratha and Gnanamanickam 1990) or spontaneous avirulent mutants of *P. solanacearum* (Mc Laughlin et al. 1990; Tanaka et al. 1990), but these met with limited success.

We began to investigate the use of genetically-defined, avirulent mutants of *P. solanacearum* for biological control. For this purpose we have employed Tn5-induced *hrp* mutants (Boucher et al. 1985) that retain the ability to colonise tomato plants without causing disease (Trigalet and Demery 1986). Preinoculation of tomato plants with these avirulent mutants has been correlated with decreased disease severity upon challenge inoculation with a wild type, virulent strain. Furthermore, Tn5-induced mutants were able to exclude the virulent strain from the susceptible host (Trigalet and Trigalet-Demery 1990).

Recently, we have constructed a new series of avirulent mutants by inserting the Ω–Km interposon adjacent to the site of one of the original Tn5 insertions (Marie 1989). Three such mutants, each derived from a different virulent strain of *P. solanacearum* isolated on Guadeloupe, were examined for the ability to control bacterial wilt and for their effect on fruit yield. The experiment was conducted in a contained environment on the island of Guadeloupe (French West Indies), where bacterial wilt is endemic.

Materials and Methods

Construction of avirulent mutants. We have previously determined that, of the original Tn5-induced *hrp* mutants of *P. solanacearum* (Boucher et al. 1985), strain GMI 1353 showed greatest potential as a biocontrol agent (Trigalet and Trigalet-Demery 1990). Therefore, using GMI 1353 as the prototype strain, we constructed a new series of *hrp* mutants by insertion of the Ω–Km interposon (Fellay et al. 1987) at an EcoRV site near to the Tn5 insertion site in GMI 1353 (Marie 1989). Like GMI 1353, these Ω–Km mutants were avirulent on tomato plants and still able to multiply within the host plant. We used the Ω–Km interposon in order to avoid transposition-associated reversion which is potentially a problem with Tn5-induced mutations. The characteristics of the bacterial strains are given in Table 1.

Table 1. Characteristics of the bacterial strains.

Code number	Characteristics	Reference or source
Virulent strains		
GA2	Wild type (eggplant, Guadeloupe, 1986)	Prior and Steva (1990)
GA4	Wild type (eggplant, Guadeloupe, 1983)	Prior and Steva (1990)
GT4	Wild type (tomato, Guadeloupe, 1984)	Prior and Steva (1990)
GT1	Wild type (tomato, Guadeloupe, 1985)	Prior and Steva (1990)
GMI 8217	Spontaneous Sm^R Rif^R derivative of GT1	A. Trigalet
Avirulent strains		
GMI 8171	Ω–Km-induced derivative of GA2	Marie (1989)
GMI 8172	Ω–Km-induced derivative of GA4	Marie (1989)
GMI 8173	Ω–Km-induced derivative of GT4	Marie (1989)

Inoculum. Bacteria were grown at 30°C on peptone medium (bacto-peptone 10 g, glucose 5 g, yeast extract 1 g, casamino-acids 1 g, distilled water 1 L; solid medium supplemented with Bacto-agar 15 g, triphenyltetrazolium chloride 50 mg, and the following antibiotics: kanamycin (Km) 50 mg, streptomycin (Sm) 200 mg, rifampicin (Rif) 50 mg). Inoculum was prepared from 24-hour broth cultures by adjusting the bacterial density with distilled water.

Plant material and root inoculation. The experiments were conducted in a contained environment on Guadeloupe during two separate seasons (cool season—November–April, 20°–27°C night/day; warm season—May–October, 23°–29°C). Susceptible tomato plants (cv. Floradel) were grown in 7×7 cm pots containing steam-disinfected greenhouse soil. For root inoculation with the avirulent mutants, 3–4-week old plants were soaked in a bacterial suspension (2×10^9 cfu/mL) for 5 minutes. Four weeks later, the plants were challenge inoculated with the virulent strain GMI 8217 (3 mL per plant of an inoculum of about 10^7 cfu/mL was poured onto the wounded roots).

Bacterial isolation tests. To monitor bacterial populations in planta, 2 cm stem segments were surface-sterilised and placed in 5 mL sterile distilled water at 10°C for 12 hours. Bacteria which streamed from the xylem vessels were counted following dilution plating on selective medium. Bacterial densities obtained with this method were not significantly different from those obtained after crushing the stem segments.

Symptoms and yield notations. Bacterial wilt symptoms were assessed according to the disease index (DI) scale of Winstead and Kelman (1952). Yield parameters (number of flowers per plant, number of fruits per plant, mean weight per fruit, yield per plant) were recorded during cool and warm seasons on plants inoculated with avirulent mutants GMI 8171 and GMI 8172, respectively, and on non-inoculated plants.

Bacteriocin production. Direct antagonism between avirulent and virulent strains was studied. Ten microlitres of a bacterial suspension or filtrate (pore size = 0.22 µm) of a producer strain was spotted on a bacterial lawn of an indicator strain. After incubation at 30°C for 24 hours, the diameter of the inhibition zone was measured.

Results

Colonisation of tomato plants by avirulent strain GMI 8172. Three months after root inoculation with strain GMI 8172, corresponding to the end of the fruit production period, bacteria were isolated at six points within the plant (taproot, collar, mid-stem, 1st, 2nd and 3rd peduncle). Avirulent bacteria were detected in taproot (8.51 log cfu/g dry weight) and collar tissues (5.66 log cfu/g dry weight) only. They were never detected in the mid-stem tissue, or in peduncle tissue. This contrasts with the virulent bacterium, which spreads systemically throughout the diseased plant.

Effect on fruit production. Experiments performed during cool and warm seasons showed that the yield parameters of tomato plants inoculated with avirulent mutants GMI 8171 or 8172 were not significantly different from those of non-inoculated plants.

Colonisation of tomato plants after inoculation with avirulent strains GMI 8171, 8172 or 8173 and challenge inoculation with virulent strain GMI 8217. The three avirulent mutants colonised the collar tissue at much lower densities than the virulent strain (Table

2). Nevertheless, preinoculation with the avirulent strains GMI 8171 or GMI 8172 was correlated with a significant reduction in colonisation by the virulent strain GMI 8217. This was not the case with avirulent strain GMI 8173, consistent with the lower protection rate obtained.

Bacteriocin production. We showed that the virulent strain GMI 8217 produces, in vitro, a bacteriocin active against the three avirulent mutants and against numerous wild type strains of *P. solanacearum* collected in Guadeloupe. This bacteriocin is also produced in planta in tomato stems infected with strain GMI 8217.

Conclusions and Perspectives

Tomato plants that were inoculated with Ω–Km-induced avirulent mutants exhibited reduced disease severity upon subsequent challenge inoculation with virulent *P. solanacearum*. Importantly, inoculation with the avirulent mutants did not have a detrimental effect on fruit yield. Challenge inoculation experiments with the virulent strain GMI 8217 led to unexpected results because the three avirulent mutants were unable to exclude the virulent strain from colonising the tomato stem. In collar tissue from coinoculated plants, the virulent bacteria were consistently 5 or 6 orders of magnitude more abundant than the avirulent mutants. However, in the case of the avirulent mutants GMI 8171 and GMI 8172, protection was correlated with a significant reduction in multiplication of the virulent strain GMI 8217. The relative overabundance of virulent bacteria in double-inoculated tissue makes direct antagonism and competition for available resources unlikely mechanisms for control of disease; thus, we consider that protection could result from the induction of host resistance mechanisms.

We have determined that the virulent strain GMI 8217 produces a bacteriocin that is active against numerous strains of *P. solanacearum*, including the three avirulent mutants used in these experiments. This result may explain the low protection rates we obtained. As avirulent bacteriocin-producing strains of *P. solanacearum* are potential biocontrol agents against bacterial wilt (Chen and Echandi 1984; Hara and Ono 1991), it may be informative to test in future experiments avirulent *hrp* mutants that have bacteriocin-resistant and/or bacteriocin-producing phenotypes.

For several reasons (including the influence of the contained environment, distribution and concentration of applied inoculum, abiotic factors) these experiments did not reproduce the conditions under which bacterial wilt occurs in nature. Therefore, to further examine the efficacy of these *hrp* mutants as biological control agents, additional tests must be conducted under field conditions where infection by the pathogen occurs naturally.

Antibiotic-Induced Virulence and Changes in Colony Morphology of *Pseudomonas solanacearum*

A.V. Gadewar, G. S. Shekhawat and S. K. Chakrabarti*

Abstract

Afluidal variants of *Pseudomonas solanacearum* in the present studies gave fluidal revertants spontaneously. Both of the antibiotics terramycin and tetracycline increased the number of fluidal revertants by 5- to 16-fold. The conversion of afluidal cells to fluidal cells was triggered by antibiotics. The cells thus converted behaved in the same manner in their growth and pathogenicity as the normal fluidal cells. After plating suspension of avirulent colonies on tetracycline-amended TZC agar plates, all the colonies appeared afluidal up to 48–72 hours of incubation but at 96 hours the fluidal and afluidal colonies could be distinguished. Terramycin reduced total number of colonies by 19.5 and 53% at concentrations of 5 and 10 µg/mL of the medium, respectively. Tetracycline at concentrations of 3 and 4 µg/mL of the medium reduced the total number of colonies by 46.6 and 71%, respectively.

ANTIBIOTICS are widely used to prevent and control bacterial disease in animals and humans. Limited kinds of antibiotics, mostly streptomycin and oxytetracycline, in combinations or separately are also used to control bacterial plant diseases. These or other inhibitory antibiotics are not known to induce or increase the virulence of the target plant pathogenic bacteria. Often, however, a normally effective antibiotic fails to control these diseases. Such failures are mainly attributed to the prevalence of resistant strains, bad weather, reduced efficiency of the antibiotic, heavy inoculum load etc., though resistant strains have not been prevalent (Loper and Henkel 1991)

Pseudomonas solanacearum causes rapid wilt of foliage in many economically important plants in the tropics and subtropics, including potato, tomato, eggplant, banana, and eucalyptus. Wild types of the pathogen producing extracellular polysaccharide (EPS+) undergo irreversible conversion to produce weakly virulent or avirulent variants spontaneously *in vivo* and *in vitro*. The fate of these avirulent forms in nature is not known. However, Buddenhagen (1986) and Brumbley and Denny (1990) postulated that these avirulent forms may be converting to virulent forms under some kind of stimulus. Recently we found spontaneous reversions of avirulent forms to the virulent forms in two isolates (Shekhawat et al. 1992). The results contained in the present paper show that the rate of reversion is enhanced in presence of the antibiotics terramycin and tetracycline.

*Division of Plant Pathology, Central Potato Research Institute, Shimla 171 001, India.

Materials and Methods

Isolate of *P. solanacearum*

The isolate GSC 26A in which spontaneous reversion of afluidal forms to fluidal forms has been reported was used. Afluidal colonies selected in earlier studies were further purified for 150 consecutive generations in succession in the following way on tetrazolium (TZC) agar medium (Kelman 1954) incubated at 30°C. On each occasion a well isolated, 72-hour-old afluidal colony was picked into 10 mL of sterilised water, allowed to stand for 1 hour, vortexed for 10 minutes and subsequently 10-fold serial dilutions were made in 9 mL of sterile water. All the dilutions were vortexed for 10 minutes. One tenth of a millilitre of 10^{-5} dilutions was spread on individual TZC agar plates. A fluidal clone obtained in the 150th generation and its subsequent descendants were used in the present studies.

TZC agar medium containing glucose as carbon source was used throughout. Plates were dried in

inverted position at room temperature before use. Fluidal wild types and afluidal weakly virulent forms of *P. solanacearum* were identified on this medium and further tested for pathogenicity.

Antibiotics

Pharmaceutical preparations (meant for human use) of chloromycetin (chloramphenicol, Parke Davis), terramycin (oxytetracycline hydrochloride, Pfizer Ltd), and ambistryn-S (streptomycin sulphate, Sarabhai Chemicals), pure vancomycin (vancomycin hydrochloride, Sigma), and tetracycline (tetracycline hydrochloride, Hindusthan Dehydrated Media, India) were used. Cooled TZC medium was amended with these antibiotics separately to give desired concentrations.

Preliminary studies on effect of antibiotics on reversion phenomenon

Initially, the effect of antibiotics on reversion was studied on TZC agar medium containing chloromycetin, 50 µg/mL; vancomycin, 30 µg/mL; ambistryn-S, 30 µg/mL and terramycin, 10 µg/mL. The results of these studies were confirmed by repeating the trial. Five repeated trials consisted of terramycin 1, 2, 5, 10, 15, 20, 25 and 30 µg/mL of TZC agar and tetracycline 1 to 5 µg/mL of TZC agar. Each time one colony formed one trial.

In every trial, one 72-hour-old afluidal colony was picked from TZC agar plate and mixed in 10 mL of sterilised water. Ten-fold serial dilutions were made as above. From 10^{-5} dilution, 100 mL of suspension was spread on TZC and antibiotic amended plates, and incubated at 30°C. Two plates for each concentration of an antibiotic were used. Observations on colony types were recorded. Further extensive studies were carried out using terramycin and tetracycline as given below.

Enumeration of fluidal and afluidal clones obtained from single afluidal colonies on TZC, terramycin- and tetracycline-containing plates

In a bacterial suspension the bottom layer may tend to have more cells and also the top layer may contain more avirulent cells of *P. solanacearum* due to aerotaxis (Kelman and Hruschka 1973). To nullify the effect of such variations, the dilution (10^{-5}) was divided into six parts starting from top to bottom. From each part, 0.1 mL suspension was spread to each of TZC and terramycin (5 and 10 µg/mL) -amended plates. This way six plates of each treatment received 0.1 mL suspension individually. The same procedures were repeated on the TZC plates containing tetracycline (3 and 4 µg/mL). These experiments were repeated by taking nine afluidal clones using terramycin and seven times taking tetracycline. Afluidal clones obtained on TZC in preceding trials were used in subsequent trials.

Reversions in afluidal clones obtained from antibiotic plates

Ten afluidal colonies were picked from each TZC plate containing each antibiotic concentration in sterile water separately, and reversion percentages were recorded on two TZC plates using dilution plate techniques as described above.

Studies with afluidal clones obtained from plants

One-month-old tomato seedlings were inoculated with afluidal clones obtained from TZC plates. Ten 72-hour-old colonies were used in this experiment. One plant received suspension obtained from one colony. Plants were inoculated by stem-stab methods and incubated in the glasshouse for 15 days at 30°C. On the 15th day, middle portions (1 cm) of these plants were suspended in sterilised water in glass test tubes separately and the suspensions were plated on TZC plates. Five afluidal colonies were picked from each plate, purified and reversion percentage was determined by dilution plate technique as described above.

Antagonism between afluidal and fluidal cells

Seventy one-hour-old fluidal and afluidal clones obtained from single afluidal clones were picked separately in 10 mL of water . Suspensions obtained from fluidal and afluidal colonies were streaked on the same plate, crossing each other at an angle of 90°. Observations for inhibition were recorded from 24 hours onwards. The experiment was repeated four times with different clones and dilutions of bacterial suspensions.

Pathogenicity tests with fluidal and afluidal forms from TZC and fluidal forms from terramycin and tetracycline plates

Pathogenicity tests were carried out on 4-week-old (after transplanting) healthy tomato seedlings (cv. Pusa Ruby, highly susceptible to *P. solanacearum*). Inoculum was prepared by taking 10 fluidal and 20 afluidal colonies from 72 hours growth on TZC and 18 fluidal colonies from 92 hours growth on terramycin (10 µg/mL)-containing TZC plates. Fluidal colonies obtained from terramycin plate were from a single plate so that spontaneous and terramycin-induced convertants are included in the test. Individual colonies were suspended in 1 mL of sterilised water separately. After vortexing, each suspension was divided into two parts. From one part, total viable counts of fluidal and afluidal forms were made on TZC plates. The other half

of the suspension was used to inoculate two tomato seedlings using the stem-puncture method (Winstead and Kelman 1952). The plants, along with those inoculated with water, were incubated at 30°C in a glasshouse. Severity of the disease and wilt indices were calculated as described by Winstead and Kelman (1952).

In similar manner, 10 fluidal colonies were obtained from tetracycline (4 µg/mL)-containing TZC plate and their pathogenicity was compared with 10 afluidal and 10 fluidal colonies from TZC plates.

Antibiotic dependent fluidity and growth of fluidal clones

Eighteen and 10 fluidal colonies from terramycin (10 µg/mL) and tetracycline (4 µg/mL)-containing TZC agar plates, respectively, were used for pathogenicity trials. It was not known whether the fluidity in colonies was due only to the presence of the antibiotic in medium, and the cells required antibiotic to produce EPS, or whether it was an inherited property of bacterial cells. Estimates of the fluidal and afluidal cells were made in colonies from antibiotic containing and plain TZC plates for comparison. Twenty-eight fluidal colonies were used for pathogenicity test from antibiotic plates and 20 fluidal colonies from TZC plates. They were plated for 10 subsequent generations on TZC plates to assess stability of the fluidity and the total viable cells.

Statistical analysis

Experiments on individual colonies were arranged in randomised design. Data on fluidal, afluidal, total and percent fluidal clones from each colony replicated six times was statistically analysed adopting randomised block lay out. The intra-colony errors were tested for homogeneity using Barlett's test of homogeneity and data were pooled over the colonies. Treatment, colony and treatment interactions were tested against the pooled intra-colony error mean square, while the colonies were tested against the pooled intra replicate mean squares.

Results

Purifications of the mother clone

Diluted suspensions obtained in 150 successive progeny afluidal clones gave fluidal revertants every time in the range 1.2–5.5%. This indicated that ability to revert is not lost even after 150 generations.

Effect of antibiotics on reversion phenomenon

In the initial trials diluted suspension (10^{-5}) obtained from two afluidal colonies at two different times gave total colony forming units (cfu) in the range of 82–115 in each plate of TZC and the number of fluidal colonies ranged from 2–6. At the same time, equal parts of the same suspensions when spread on the TZC plates containing chloromycetin, ambistryn-s and vancomycin gave 2–7 fluidal colonies. However, the number of the fluidal colonies ranged from 15–48 in the plates containing terramycin (10 µg/mL of TZC medium).

Trials with lower concentrations of terramycin (1–4 µg/mL) and tetracycline (1 and 2 mg/mL) did not increase the frequencies of fluidal revertants significantly, while the higher concentrations of terramycin (15–30 µg/mL) and tetracycline (5 µg/mL) reduced the total colonies to the extent of 90%. Terramycin (5 and 10 µg/mL) and tetracycline (3 and 4 µg/mL) gave consistent increase in fluidal colonies and the reduction in total population was also relatively low (Tables 1 and 2) and therefore these concentrations were used in subsequent trials.

Reversions in the afluidal clones obtained from antibiotic plates

Afluidal colonies, obtained from TZC agar plates containing each concentration of chloromycetin, ambistryn-s, vancomycin, terramycin and tetracycline showed revertant fluidal clones in the range of 1.0–6.9%. This also indicated that reversion character is not affected by antibiotics.

Reversions in afluidal clones obtained from plants

Fifty afluidal forms obtained from 10 plants showed revertant fluidal forms in the range 1.0–4.9%. This indicated that the phenomenon of reversion was not affected by passage through the host.

Enumerations of fluidal and afluidal clones obtained from single afluidal colonies on TZC, terramycin- and tetracycline-containing plates

On TZC plates mean number of 3.3 out of 135.3 cells formed fluidal colonies (Table 1 and Fig. 1). However, in the plates amended with 5 and 10 µg/mL terramycin the mean numbers of fluidal colonies were 16 and 52.7, respectively. Both concentrations of antibiotic reduced the total number of the colonies significantly, by 19.5% and 53.1% in 5 and 10 µg/mL terramycin plates, respectively. Distinct afluidal and fluidal colonies were formed between 48 and 72 hours in TZC and terramycin (5 µg/mL)-containing TZC plates. However, on 10 µg/mL terramycin the colonies appeared between 72 and 94 hours.

On TZC plates, a mean number of 3.8 of 113.6 colonies was fluidal (Table 2). However, in TZC plates amended with 3 and 4 µg/mL tetracycline, mean numbers of fluidal colonies were 28.9 and 25.36, respec-

Table 1. Mean number of colonies on each TZC and terramycin-amended medium from 10 afluidal colonies of *P. solanacearum* and their conversion to fluidal form.

[a](Fluidal × 100)/total.
[b]Significant at 1% probability level.
[c]Total sum of squares are in original units. The treatment component of variation in the ANOVA explained the major portion of total variability in each of the attributes. The colonies differed significantly from each other in the overall level of attributes. The treatments interacted with the colonies in their responses but the magnitude of interaction was small.

Fig. 1. Equal amount of suspension (0.1 mL of 10^{-5} dilution) obtained from single afluidal colony (72 hours old) of *P. solanacearum* was spread on each plate of TZC and TZC containing terramycin. Top single plate TZC containing 10 µg/mL terramycin. Lower left TZC plate (control). Lower right TZC plate containing 5 µg/mL terramycin. Terramycin containing plates show decreased numbers of total colonies but significant increase in numbers of fluidal colonies as compared to fluidal colonies in control plate.

tively. Reduction in the total number of the colonies was 46.6% and 71% in 3 and 4 µg/mL tetracycline, respectively. Fluidal and afluidal colonies in tetracycline plates looked alike between 72 and 96 hours. They were red, round and compact with a thin white margin but after 24 hours further incubation colonies grew and fluidity was visible in the periphery of some colonies (Figs 2–4). They were slightly raised and change in colony colour from deep red to pink was visible. Such colonies consisted almost entirely of fluidal cells (90–100%).

Antagonism between afluidal and fluidal cells

Repeated trials with fluidal and afluidal clones obtained from single mother clones revealed no antagonism between them. Moreover, it was sometimes observed in dilution plating that fluidal and afluidal colonies grew side by side without antagonism.

Pathogenicity tests of fluidal and afluidal colonies

Fluidal colonies from TZC, terramycin (10 µg/mL) and tetracycline (4 µg/mL)-amended plates were found to

Fig. 2. Equal amount of suspension from a single afluidal colony was spread on TZC and tetracycline-amended plates. Appearance of afluidal and few revertants on TZC plate (left). Fluidal revertants on tetracycline plate (right) were red pigmented, compact, more or less round and with broad white margin.

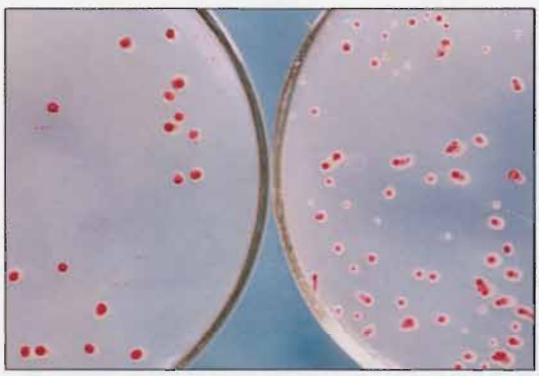

Fig. 3. Suspension from a single afluidal colony was spread on tetracycline-amended plates. Variations in fluidal revertant colonies. Two red colonies without white broad margin in plate at left were afluidal.

cause wilt in tomato plants (Tables 3 and 4). However, afluidal forms from TZC plates caused only slight wilt. This was expected because such afluidal colonies contained few fluidal cells (1.63–3.81%). Initially, plants inoculated with afluidal colonies showed slight wilt but some of them recovered completely. This indicated that fluidal forms in presence of a high number of afluidal forms in the same inoculum were unable to cause complete wilt.

Antibiotic dependent fluidity and growth of the fluidal clones

Fluidal colonies from TZC, terramycin and tetracycline plates contained almost equal numbers of fluidal cells

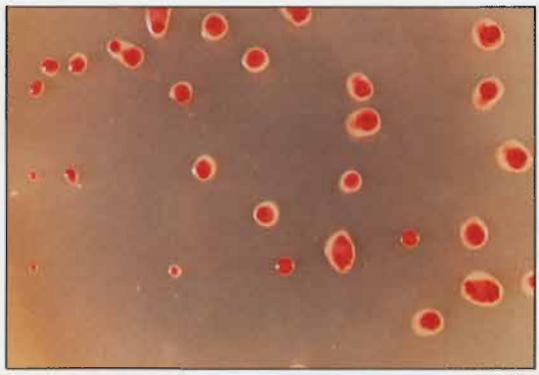

Fig. 4. Suspension from a single afluidal colony was spread on tetracycline-amended plate. Close up of fluidal revertants and afluidal nonrevertants.

(10^7–10^8) (Tables 3 and 4) during the next 10 generations. Thus, the virulence and fluidity induced by the antibiotic was stable.

Discussion

Fluidal virulent forms of *P. solanacearum* are known to change into afluidal avirulent forms spontaneously. The afluidal forms are believed to be stable and are not known to revert to wild type. The bacterial cells from these colonies are expected to give only afluidal progeny clones unless the colony has originated from mixture of fluidal and afluidal cells. However, in the present studies, afluidal forms obtained from TZC, antibiotic-amended plates and plants gave mixed afluidal and fluidal clones. Chances of mixture were ruled out because a dilution plate technique was used to purify a single mother clone and the purification was repeated over 200 generations before the start of the experiment. Distinct well-isolated colonies were selected after 72 hours of incubation to allow growth of all the cells and late appearing clones if any could be detected on TZC plates. Serial dilution accompanied by vortexing for 200 generations is expected to separate bacterial cells from each other and the single colonies are expected to arise from individual cells. Moreover, if the cells existed in groups of two or more due to the presence of polysaccharides, each living cell would have grown on TZC medium which supports good growth of fluidal and afluidal cells. There was no inhibition between fluidal and afluidal forms in the present studies as also reported by earlier workers (Averre and Kelman 1964). In such a situation twin cells (fluidal and afluidal) present at the same spot in the medium would have given twin coalesced colonies, easily identifiable

Table 3. Mean number of colonies on each TZC and tetracycline-amended medium from 7 afluidal colonies of *P. solanacearum* and their conversion to fluidal form.

Treatment	Number of colonies			Fluidal[1]	Reduction[2]	Conversion[3]

[c]Total sum of squares are in original units. The treatment component of variation in the ANOVA explained the major portion of total variability in each of the attributes. The colonies differed significantly from each other in the overall level of attributes. The treatments interacted with the colonies in their responses but the magnitude of interaction was small.

by monitoring growth since the initiation, and also later by observing colonies with the naked eye or under the microscope. In the present studies colonies were monitored for initiation and growth (approximately 36 hours onwards) and no mixed colonies were used.

A maximum of 97.5% afluidal cells and a minimum of 2.5% fluidal cells were detected on TZC in a suspension obtained from single afluidal colony (Table 1). There is a possibility that all the 97.5% afluidal colonies originated from afluidal and fluidal twins but growth of afluidal cells was rapid and hindered growth of fluidal cells and therefore colony type was afluidal. This was considered by conducting pathogenicity tests using susceptible tomato plants. Suspensions were obtained from single afluidal colonies separately. One part of the suspension was used to estimate viable counts and another part was used to inoculate the plants. Suspensions from afluidal colonies consisted of 1.81–3.81% and 1.63–3.42% fluidal cells in two separate trials (Tables 3 and 4). No plant showed complete wilt. Had there been more fluidal cells, or fluidal and afluidal cells in the form of twins, wilting of tomato plants was certain because all the cells have equal opportunity of growth in the plant system. Inoculum consisting of a 50:50 proportion of afluidal and fluidal cells is known to cause wilting in the plants (Averre and Kelman 1964). Plant inoculation tests also indicated that the suspension contained only a few fluidal cells. The possibility of the occurrence of twin cells (fluidal and afluidal) was therefore remote.

The foregoing discussion established that the afluidal cells of the present isolates were unstable and gave rise to fluidal cells while growing. When suspensions obtained from afluidal colonies were spread on terramycin and tetracycline plates, there was a 5- to 16-fold increase in number of fluidal colonies. This increase in number of fluidal colonies could be due to: (1) dependence of fluidal clones present in the inoculum on the antibiotics for growth and (2) increase in frequency of spontaneous reversion in presence of antibiotic.

Table 5. Disease index (DI) in tomato plants inoculated with fluidal (FL), afluidal (AFL) and terramycin-induced fluidal colonies 7, 14, and 21 days after inoculation (DAI).

Colony type and source	No. of colonies/ plants inoculated	DI/DAI 7	14	21
AFL from TZC[a]	20/40	2.0	5.0	5.5
FL from TZC[b]	10/20	5.0	20.0	72.0
Terramycin (10 µg/mL)-induced FL[c]	18/36	14.4	44.4	67.2

[a]Afluidal colonies from TZC consisted of total cfu in the range of 1.1–4.1 × 10^8 and fluidal cells 1.81–3.81%.
[b]Fluidal colonies from TZC consisted of total cfu in the range of 3.3 × 10^7 to 7.9 × 10^8 and afluidal cells 0–6.3%.
[c]Fluidal colonies from terramycin plate consisted of total cfu in the range of 4.1 × 10^7 to 6.8 x 10^8 and afluidal cells 0–11.1%.

Table 6. Disease index (DI) in tomato plants inoculated with fluidal (FL), afluidal (AFL) and terramycin-induced fluidal colonies 7, 14, and 21 days after inoculation (DAI).

Colony type and source	No. of colonies/ plants inoculated	DI/DAI 7	14	21
AFL from TZC[a]	10/20	2.0	4.0	6.0
FL from TZC[b]	10/20	19.0	59.0	93.0
Tetracycline (4 mg/mL)-induced FL[c]	10/20	35.0	71.0	96.0

[a]Afluidal colonies from TZC consisted of total cfu in the range of 1.1–3.8 × 10^8 and fluidal cells 1.6–3.42%.
[b]Fluidal colonies from tetracycline plates consisted of total cfu in the range of 4.5 × 10^7 to 3.5 × 10^8 and fluidal cells 0–9.1%
[c]Fluidal colonies from TZC consisted of total cfu in the range of 9.8 ×10^7 to 3.2 × 10^8 and fluidal cells 0–7.7%.

There are reports that some mutant cells of *Escherichia coli* and other bacteria are dependent on streptomycin for growth (Paine and Finland 1948; Newcombe and Hawirko 1949). They occurr at very low frequencies. Similarly, carbenicillin is used for the selection of rare natural mucoid revertant from the nonmucoid cultures of *P. aeruginosa* (Govan et al. 1979).

In the present studies, increase in the number of fluidal revertants was consistent in the terramycin and tetracycline plates in all the colonies so far studied. The experiments were repeated over a hundred times with different single colonies (data not shown). Therefore it is not a rare phenomenon.

Dependence of fluidal cells from fluidal colonies on antibiotic(s) for growth was studied by spreading almost all the colonies from the terramycin (10 µg/mL) and tetracycline (4 µg/mL) single plates. Total number and types of cells were similar to those present in fluidal colonies from TZC plates. Further, their descendant clones grew very well and maintained fluidity in a subsequent 10 generations studied on the TZC plates. There are reports that *E.coli* cells accumulate oxytetracycline and cells become yellow. Liquid cultures become turbid without the growth of the cells (Arima and Izaki 1963). In our study, individual resistant fluidal and afluidal cells multiplied in the presence of terramycin (oxytetracycline) and fluidity was maintained in subsequent generations in the absence of the antibiotic. Fluidity was therefore not due to the antibiotic accumulation but rather to inherent capacity of the cells to produce fluidity in the colonies. Fluidal cells from fluidal colonies grown on antibiotic were at par with fluidal normal cells not exposed to antibiotic in respect of their capacity to cause wilt of tomato plants. It can be concluded that the increased number of colonies on antibiotic plates compared to TZC plates was not dependent on the antibiotics for growth and fluidity. Afluidal cells present in the inoculum reverted to the fluidal cells under the influence of the antibiotic.

Genetic instability in microorganisms is known to be due to legitimate and illegitimate rearrangement and recombinations (Auerbach 1976; Anderson and Roth 1977; Nevers and Saedler 1977). Tetracycline is known to interfere with aminoacyl t-RNA binding or peptide bond formation (Benveniste and Davies 1973). Exposure of bacteria to subinhibitory concentrations of antibiotic(s) is known to cause amplification in resistance factors present in the plasmids (Franklin and Rownd 1973; Clewell et al. 1975) and when the determinant is transposon-borne, the activity of the transposition increases (Tomich and Clewell 1980). Which mechanism is operating in the reversion phenomenon is not known.

Disease Management: Biological and Cultural Methods

Management of Bacterial Wilt of Tobacco

E. Akiew, P.R. Trevorrow* and P.E. Tonello†

Abstract

Bacterial wilt caused by *Pseudomonas solanacearum* poses a major threat to flue-cured tobacco crops in Queensland. Breakdown of field resistance has been observed and yield losses were estimated in the range 10–90%. Certain *P. solanacearum* strains from hosts other than tobacco were virulent on resistant tobacco cultivars and breeding lines. A rapid-screening technique was developed and used to assess tobacco breeding lines for resistance to several local strains of *P. solanacearum* prior to agronomic evaluation. The results of ecological studies and resistance developed in the local breeding program have been used to devise control measures. In conjunction with resistance, most farmers adopted a 2–3 year rotation with signal grass (*Brachiaria decumbens*), destruction of stubble, and the control of nematode and weeds to reduce disease incidence. Early planting of resistant cultivars is practiced and this significantly reduced losses where bacterial wilt had previously occurred. Alternative approaches (non-chemical) for the management of tobacco bacterial wilt are being investigated.

BACTERIAL wilt of tobacco (*Nicotiana tabacum L.*) occurs in tropical countries and in some tobacco-growing areas with a maximum temperature of 30–35°C during the cropping season. Moderate to severe crop losses have occasionally been reported (Akiew and Trevorrow 1990; Chiang et al. 1990; Engelbrecht and Prinsloo 1985; Melton et al. 1988). The disease is serious when tobacco is grown each year on the same land.

The symptoms of bacterial wilt of tobacco appear on young infected plants as one or two leaves drooping during hot days, often only half of a leaf becoming flaccid. The wilting of leaves on one side is a characteristic symptom. These symptoms develop slowly when day temperatures do not exceed 30°C. Affected leaves become light green, gradually turn yellow and show necrotic areas between the veins and at the leaf margins. Rapid development of the disease occurs with temperatures above 30°C and causes severe wilt without change in colour of the wilted leaves. Dry, hot weather causes irregular scalding of the affected leaves.

The stem near the base shows brown to black streaks in the woody vascular tissue. One or two of the roots show advanced state of decay, becoming dark brown to black. Severely diseased plants have most if not all of the roots completely decayed. The diagnostic sign of the disease is similar to that on other hosts.

Unlike tomato and other solanaceous crops, tobacco has been successfully grown in areas with bacterial wilt. Plant resistance, in conjunction with improved cultural practices, has been used to manage the disease. Effective management programs for tobacco-based farming systems are generally derived from local research. Some of the recommended management programs are reviewed in this paper.

Production of Healthy Seedlings

The production of uniform and healthy tobacco seedlings provides the basis for a successful tobacco crop. Many diseases of tobacco in the field may originate from poorly managed and disease-infested seedbeds. Some disease outbreaks have been associated with seedlings carrying latent infection of soilborne pathogens like *P. solanacearum*.

The seedbed site must be well drained, sheltered from prevailing winds and free of shading from trees or buildings. It should also be fenced and far from other solanaceous crops. A wide area around the seedbeds should be ploughed and kept free of weeds. All equipment used in the seedbeds, including sand and

*Plant Protection Division, Queensland Department of Primary Industries, Mareeba, Queensland 4880, Australia.
†Crop Science Division, Queensland Department of Primary Industries, Mareeba, Queensland 4880, Australia.

cracked gravel, should be sterilised before being introduced into the fumigated seedbed. Plant beds should run across the slope to minimise erosion, and raised 10–15 cm above a pathway to facilitate drainage. A rotational system, incorporating forage sorghum (*Sorghum* spp.) or other non-host plants, enabling tobacco seedlings to be grown in the same site only once every three to four years, is recommended (Tonello and Gilbert 1990).

Seedbed disinfection before sowing is mandatory for successful production of seedlings. A liquid mixture of methyl bromide and chloropicrin will control soilborne pathogens and weed seeds. The fumigant is injected 13–18 cm into the soil with a tractor-mounted chisel-type applicator and a plastic cover is placed directly on the treated bed and the edges sealed into the soil immediately after application. The recommended rate per bed area depends on the soil type; heavier and more compact soils require higher dosages. The rate in Australia is 3.5 kg/36 m^2, which is slightly higher than that recommended by Lucas (1975). Fumigation begins about midday when high temperature speeds up the release of the gas and its entry into the soil. After 24–36 hours, the gastight cover is removed and the soil aerated before sowing. Should rain fall during this period, the soil is aerated by chipping the top 10 cm.

Burning wood or other materials on the beds heats the soil and kills weed seeds and soilborne pathogens. This method is applicable and useful in many developing countries where chemical fumigants are either expensive or unavailable. Sometimes, formaldehyde solution is used as a drench to control diseases caused by bacteria and fungi.

Plant Resistance

The most successful control of bacterial wilt of tobacco in countries such as Australia has been through the development and the use of resistant varieties of tobacco. Progress has been made in the selection of tobacco lines with high resistance to the disease (Gillham and Harrigan 1977; Hansen 1990; Kelman 1953; Lucas 1975; Nakamura et al. 1974). Recently, somaclonal variation has been used to develop somaclones, of which some show higher resistance to bacterial wilt than their parents (Daub and Jenns 1989). There is scope for the use of genetic engineering to develop tobacco varieties with high levels of resistance to this disease.

Wilt-resistant cultivars with good agronomic qualities are widely grown in areas where bacterial wilt is a major problem. These are grown in rotation with crops such as maize or soybean to achieve long-term control of the disease. Resistance alone is not recommended because of the potential for a change in the pathogen towards a more virulent population, as has been observed in many tobacco-growing areas in the tropics.

In north Queensland, Australia, bacterial wilt was detected on the resistant tobacco cultivar ZZ100 after two successive years of cultivation in which moderate to severe losses have subsequently been recorded in infested fields. Moreover, virulent strains of the bacterium have been isolated from wilt-resistant tobacco breeding lines undergoing field tests. The strains are more virulent than previous isolates from tobacco and other hosts, and are highly pathogenic to a resistant tobacco cultivar that has been released recently to growers.

The importance of using a standard and improved screening method to evaluate resistant breeding lines was emphasised in previous workshops (Persley 1986; Sequeira and Kelman 1976). Segregating populations are best screened under field conditions for several years, and in different areas with a history of bacterial wilt. We have developed and used a rapid and reliable method for screening tobacco seedlings for resistance to different strains of *P. solanacearum* prior to field testing (Akiew and Trevorrow 1990). The technique has been adapted for tomato and other solanaceous crops.

In areas where bacterial wilt is a problem, long-term benefits with the use of resistant cultivars could be achieved by adopting improved cultural management practices. Disease management and resistance are not separate approaches to control.

Cultural Practices

Rotations and fallow

Control of bacterial wilt by crop rotation has been extensively reported (Akiew and Trevorrow 1990; Clayton et al. 1944; Gaines and Todd 1953; Garner et al. 1917; Kincaid 1960; Lucas 1975; Melton and Powell 1991; Powell 1990; Smith 1941, 1944). These reports indicate that non-host crops in rotation with tobacco significantly reduce the incidence and severity of bacterial wilt. One-year rotation to maize (*Zea mays* L.), fescue (*Festuca* sp.) or soybean (*Glycine max* (L.) Merr.) reduces the incidence of bacterial wilt of flue-cured tobacco. Rotations using maize, cotton (*Gossypium* L.), soybeans, cowpeas (*Vigna sinensis* Savi.), velvet beans (*Stizolobium deeringianum* Bart.) or redtop grass (*Agrostis alba* L.) are recommended for the control of the disease in North Carolina. These crops are grown on wilt-infested land for 2–3 years before a tobacco crop is grown, but are not recommended for rotation in fields infested with both root-knot nematode and bacterial wilt. In Australia, forage sorghum (*Sorghum* spp.) such as cv. Jumbo and Sugar-sweet or a signal grass (*Brachiara decumbens* Stapf.)

fallow is used for rotation in many tobacco fields. However, bacterial wilt could develop on susceptible and moderately-resistant tobacco varieties when grown in summer following a host-free period of less than 2 years. The disease rarely affects winter crops despite the presence of inoculum in the soil. A 7-year rotation with signal grass significantly reduced the incidence of bacterial wilt. However, wilt incidence increased to approximately 20% when two successive crops of tobacco were grown in the same field. A cropping sequence of one tobacco crop after 2–3 years of grass fallow seems to be effective in reducing the incidence of the disease on moderately resistant varieties of tobacco. One tobacco crop after every two to three crops of sorghum is also beneficial in disease control.

The level of disease control with the use of crop rotation and fallow methods is variable, and appears to be dependent on several factors including the ability of local strains to maintain a low but infective population in the absence of a host. The bacterium is apparently a poor survivor in its free state, but could survive for at least 33 weeks in the presence of bean, maize, sorghum, peas or soybean plants (Akiew 1986; Granada and Sequeira 1983). Weeds promote the survival of the bacterium (Jackson and Gonzales 1981), whereas maize, rice and soybean reduce the population of the bacterium in the soil (Quimio and Chan 1979). Our findings on the survival of the bacterium in plots under forage sorghum and fallow for 2 years agree with these reports. The monthly population levels of the bacterium in the soil declined at a faster rate with either sorghum or grass fallow than with bare or weed fallow (Fig. 1). We have consistently recovered at least 10^2 colony forming units (CFU) per gram of soil, mostly from spots where stubbles were either retained or removed, and from the rhizosphere of the weed host, cobblers peg (*Bidens pilosa* L.). The bacterium was not equally distributed in the plot, but congregated in certain places ('hot spots') where the conditions are probably suitable for long-term survival. The numbers often dropped to almost undetectable levels during the dry winter months and increased to approximately 10^6 CFU per gram of soil during the wet season, particularly in the rhizosphere of weed hosts.

Non-host crops in rotation with tobacco have been used to manage the disease, and host-free periods of 2–3 years seem to be adequate. These are proving particularly successful in combination with resistance. Local research is needed to develop a cropping system that is suited to a particular area for the control of bacterial wilt.

Nematode and weed control

The influence of root-knot nematode (*Meloidogyne* spp.) on the development and severity of bacterial wilt

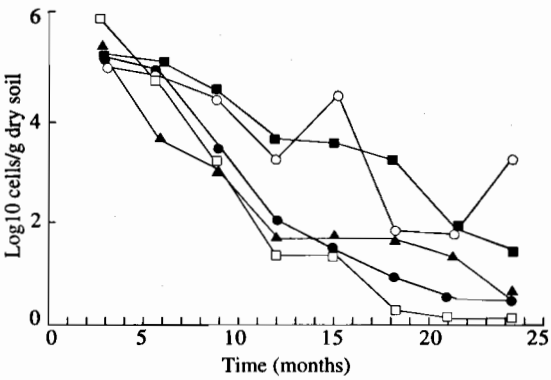

Fig. 1. Population density trends of rifampicin-resistant strains of *Pseudomonas solanacearum* (race 1, biovar III) under signal grass (❑), rhodes grass (*Chloris gayana* Kunth) (●), bare fallow (■), weed fallow (○) and forage sorghum (▲). The plots were inoculated and planted to tobacco. At the end of harvest, stubble was retained, sorghum and grass planted, and the bacterial numbers were recorded each month over two years. Sorghum was planted each spring and maintained through summer.

of tobacco has indicated that root-knot nematode infestation of tobacco roots enhances the development of bacterial wilt (Akiew et al. 1991; Johnson and Powell 1969; Lucas et al. 1955). Lucas et al. (1955) inoculated wilt-resistant plants with both root-knot nematode and *P. solanacearum*. Within 4 weeks all the plants were dead, whereas similar plants inoculated with either bacterium or nematode alone were still living and suffered much less damage. Johnson and Powell (1969) also showed that wilt-susceptible plants exposed to nematodes, then to *P. solanacearum* 3–4 weeks later developed more severe wilt symptoms earlier than when exposed to both pathogens simultaneously. Their findings are similar to the results in our study on the interaction of *P. solanacearum* and *Meloidogyne* spp. on wilt severity of a moderately resistant tobacco cultivar. Plants inoculated with both pathogens wilted earlier and to a greater extent than those inoculated with only the wilt pathogen. Disease development was more rapid and severity higher on plants inoculated with the bacterium at 10^8 than at 10^4 CFU per gram of soil. High levels of both pathogens significantly increased the severity of wilted plants.

Control of nematodes on wilt-infested land is essential to gain maximum benefits from the use of tobacco varieties with resistance to *P. solanacearum*. Effective control methods include nematode- and wilt-resistant varieties, chemical soil treatment, soil fumigation and rotation with crops that are resistant to both pathogens, such as signal grass and forage sorghum.

There are conflicting reports as to the influence of weeds in the control of bacterial wilt. The failure to eliminate weed hosts in crop rotation has been considered as one of the factors which accounts for the high incidence of bacterial wilt in a subsequent tobacco crop. However, Smith and Godfrey (1939) found no correlation between the number of susceptible weeds in one season and the severity of wilt in subsequent crops, and the weeds in a maize rotation had little effect on wilt incidence in the following year. Others suggest that weeds promote the survival of the bacterium in the soil, the carry over of inoculum to tobacco crops, and that certain weed hosts reduce the effectiveness of rotation crops (Jackson and Gonzales 1981; Melton and Powell 1991; Quimio and Chan 1979). We found a significant increase in the numbers of the bacterium in the weed-fallowed soil during the summer season when rainfall is frequent and the weed host, cobblers peg, is predominant (Fig. 1). This trend is similar to that in plots planted with tobacco each year. Severe (100% incidence) bacterial wilt developed on susceptible tobacco grown in summer after 18 months of weed-fallow.

The wide host range of *P. solanacearum* is known and many weeds could be infected by the bacterium with or without symptoms of wilt (Berg 1971; Bradbury 1986; Hayward 1986; Kelman 1953). The weeds identified in north Queensland as hosts for *P. solanacearum* include *Asclepias curassarica* L. (blood-flower), *Ageratum houstonianum* Mill. (blue billy-goat weed), *Bidens pilosa* (cobblers peg), *Calopogonium mucunoides* Desv. (calopo), *Cassia mimosoides* L. (five leaf cassia), *Citrullus lanatus* Matsum. and Nakai (paddy melon), *Corchorus acutangulus* L. (native jute), *Eclipta alba* L. (white eclipta), *Erigeron hirta* L. (asthma plant), *Lablab purpureus* L. (lablab), *Physalis* spp. (wild gooseberry), *Stachytarphita jamaicensis* L. (snake weed) and *Tagetes minuta L.* (stinking roger). Several of these weeds are symptomless, whereas others like cobblers peg show slight wilt which is evident during hot days. In India, *Ageratum conyzoides* and *Ranunculus sceleratus* show no symptoms of wilt but the bacterium is readily isolated from the roots (Sunaina et al. 1989).

Many weeds serve as alternative hosts for *P. solanacearum*, and the seasonal growth of such weeds in tobacco fields favours the maintenance of a low but infective population of the pathogen in the soil. Thus, weed fallow is not a suitable alternative to non-host crop rotation particularly on wilt-infested land. In north Queensland, herbicides are used when establishing rotation crops, ensuring a pure sward and no alternative host for the pathogen to survive on.

Other cultural practices

Stubble destruction. At the end of harvest, stalk and stubble destruction and farm hygiene are highly recommended to prevent the carry over of inoculum to subsequent tobacco crops. Studies reveal that plant debris provides temporary sheltered sites for the bacterium (Persley 1986). Graham et al. (1979) showed that plant debris could remain infected with *P. solanacearum* 33 weeks after a potato crop. As previously indicated in Figure 1, stubble retained in bare-fallowed soil maintained a consistently large number of the bacterium even during the dry season. With no stubble left in the soil, the levels dropped from approximately 10^6 to 10^3 CFU/g of soil over a period of 8 months. Severe bacterial wilt was on plants grown after 18 months of bare-fallow and with stubble retained in the soil.

Planting dates. In north Queensland, because of cool weather conditions, bacterial wilt rarely occurs on tobacco crops planted in autumn and early winter. The average maximum, and minimum temperatures during these seasons range from 24–27°C, and 11–15°C, respectively. The disease will develop on crops planted in spring particularly where bacterial wilt had previously occurred and crop rotation was not practiced. The average temperatures in spring and summer range from 17–18°C minimum and 29–32°C maximum. High temperature (30–35°C) favours the development of bacterial wilt, and the pathogen is rarely found in areas where mean temperature in typical midwinter falls below 10°C (Lucas 1975).

Biological Control

There seems to be a shift to the idea that biological control can have an important role in the management of bacterial wilt. So far, the method is commercially successful only for *Agrobacterium* control. For bacterial wilt of tobacco, strains of bacteria have been tested in the glasshouse and naturally infested fields with partial success (Akiew et al. 1991; Chen and Echandi 1984; Chen et al. 1981; Hara and Ono 1991; Lee et al. 1986; Tanaka et al. 1990). There is scope for utilising biological control as a complementary strategy to improved cultural practices and breeding for resistant cultivars.

Conclusion

Unlike other solanaceous crops, tobacco has been successfully grown in areas where bacterial wilt is one of the production constraints. This is due mainly to the success in breeding of tobacco varieties with high resistance to the pathogen, and the extensive studies on the control of the disease by cultural methods. The

recommended non-host crops and suggested host-free periods for the management of bacterial wilt of tobacco vary considerably, but a reduction of disease incidence by crop rotation is often achieved. So far, the best management program for bacterial wilt of tobacco is a combination of resistant cultivar, rotation with non-host crops, nematode and weed control, and improved farm management practices.

Integrated Control of Bacterial Wilt of Potato in the Warm Tropics of Peru

J. G. Elphinstone* and P. Aley†

Abstract

Strategies to control bacterial wilt caused by *Pseudomonas solanacearum* (race 1, biovar 1), suitable for use by smallholder potato farmers, were studied in the warm tropics of Peru. The rate of disease development was lower following a 6-month maize rotation; a 6-month fallow with a single herbicide application (metribuzin at 0.5 kg a.i. per ha); and amending soil with CaO (5 t per ha) and urea (200 kg N per ha) than disease development following a 6-month weed-infested fallow. Disease development also depended on the potato cultivar grown. However, due to high inoculum potential at the test sites, disease incidence at 90 days after planting reached excessive levels regardless of the control method used. Nevertheless, the combined application of control measures as an integrated package more effectively reduced disease incidence and increased yield. The effect of crop rotation and weed control was associated with a decline in soilborne populations of *P. solanacearum* and root-knot nematode (*Meloidogyne* spp.). The decline of *P. solanacearum* in the maize rhizosphere was related to an increased population of *P. cepacia* which was antagonistic to *P. solanacearum* in vitro. Under screenhouse conditions, soil amended with 0.5% (w/w) CaO and/or 0.1% urea prevented the development of bacterial wilt following inoculation with suspensions of the bacterium containing 10^8 cfu per mL. In hydroponic tomato seedlings, cultured under axenic conditions, a similar effect was observed when the level of either NH_4NO_3 or KNO_3 in the medium was increased from 0–16.8 or 33.6 mM. Further research is planned to study the effect of nitrogen and calcium availability on pathogenicity of the bacteria and host resistance.

ONE of the major constraints limiting potato production in the tropics is the impact of bacterial wilt caused by *Pseudomonas solanacearum*. Strategies for control of the disease on potato have been reviewed recently (Eden-Green and Elphinstone 1992; French 1988; Hayward 1991). Ideally, the problem could be avoided by ensuring that soils and planting materials are certified free of the pathogen. In practice, routine techniques used to detect the bacterium in soil and plant materials have lacked the level of sensitivity required for reliable certification procedures. Furthermore, in many potato-growing areas of the tropics, much of the available land is already infested. This is particularly true in smallholdings where land scarcity restricts crop rotation and several susceptible food crops may be produced on a regular basis (e.g. potato, tomato, pepper, eggplant, groundnut and banana). In such areas bacterial wilt can be controlled only by the combination of measures to produce healthy planting materials with measures to suppress soilborne pathogen populations.

The production of pathogen-free potato seed tubers depends on a reliable source of pathogen-free elite seed material, the identification of pathogen-free land for multiplication and the establishment of strict quarantine and certification procedures to prevent infestation of pathogen-free soils. At present, growers rely mostly on the presence or absence of symptoms to indicate whether soils and harvested tubers are pathogen-free. However, since latently-infected tubers can be produced on symptomless plants, and the tubers themselves appear healthy, there is no guarantee that a symptomless crop will yield pathogen-free progeny, particularly under cool highland conditions where symptom expression is often suppressed. The movement of infected seed-potato tubers from infested to noninfested areas continues to abet the large-scale

†International Potato Center (CIP), Apartado 5969, Lima, 100-Peru.

interregional and international spread of *P. solanacearum* throughout the tropics and subtropics.

The benefit of expensive pathogen-free seed is negated if the land available for its multiplication is already infested as a result of previously infected crops or indigenous weed hosts. Under such situations, the suppression of soilborne *P. solanacearum* is best achieved by the simultaneous application of a broad spectrum of complementary plant protection measures (French 1988). Integrated management systems incorporating the use of resistant cultivars and appropriate cropping patterns and cultural practices can alter the suitability of the microenvironment to the pathogen and hence influence disease incidence. The efficiency of a particular system is location-specific since it must be adapted to suit local climate, soil type, pathogen strain, farming system and the socioeconomic situation.

This paper describes efforts to design an integrated control system appropriate for use by smallholder table-potato farmers in land infested with race 1 (biovar 1) of *P. solanacearum* in the mid-elevation tropics of Peru. Various control measures were compared, individually and in combination, to determine their effect on the suppression of soilborne populations of the pathogen and the incidence of bacterial wilt.

Materials and Methods

Field experiments were conducted at the mid-elevation tropical field station of the International Potato Center in San Ramon, Peru (800 m above sea level, 11°S latitude). Two fields with similar soil type (sandy loam) were used during the rainy seasons (September–April) in two different years (1988–89 and 1989–90). Both fields were infested with race 1 (biovar 1) of *P. solanacearum*, having each previously been cropped with bacterial wilt-susceptible potato cultivars in which more than 80% bacterial wilt incidence was observed. Following harvest of the infected potato crops, the infested land was divided into 3 m^2 plots, each surrounded by a drainage ditch (30 cm wide and deep), in a randomised block design with five replications. To ensure uniformity of inoculum distribution in the soil, the blocks were located in areas of the field where the previous potato crop had been uniformly affected.

Three short-rotation treatments were compared to determine (a) their effect on pathogen survival and (b) the incidence of bacterial wilt when 40 susceptible (4-week-old) tomato indicator seedlings (cv. Marglobe) were transplanted into each plot after treatment. The rotation treatments were (1) 6 months crop rotation with maize cv. Chato Grande, (2) 6 months unweeded fallow and (3) 6 months vegetation-free fallow with metribuzin (Sencor, Bayer) herbicide application at a rate of 0.5 kg active ingredient per ha, at the beginning of the rotation period.

Composite samples containing 1 kg of soil from each of five sites per plot were removed from a depth of 20 cm at regular intervals during the rotation period. Rhizosphere soil, sampled from the maize and weed-infested plots was compared with non-rhizosphere soil from the herbicide-treated plots. Bacterial populations were estimated by dilution plating of the suspension in sterile distilled water of 10 g subsamples of the soil on modified Granada's SM1 selective medium (Granada and Sequeira 1983) containing 5 ppm crystal violet and 50 ppm polymixin-B sulphate as the selective ingredients. Populations in plant roots were determined by dilution plating of the homogenate of surface-sterilised roots in sterile distilled water on the same medium.

The effect of soil amendments on the development of bacterial wilt was studied under screenhouse conditions (average minimum and maximum air temperatures of 22° and 35°C, respectively) by mixing steam-sterilised compost (soil:sand:moss = 2:1:1) with either urea (0.1% by weight), powdered calcium oxide (0.5% by weight) or both. True (botanical) potato seed (TPS), from a cross between two wilt susceptible cultivars (Atzimba×R-128) was then sown in seed trays containing either amended or unamended compost. Three-week-old seedlings were inoculated by drenching the compost with a bacterial suspension containing 1×10^8 cfu/mL of the biovar 1 strain of *P. solanacearum* from San Ramon. The incidence of bacterial wilt was then monitored at regular intervals in three trays per treatment, each tray containing 50 seedlings.

Under field conditions, soil was amended in 3 m^2 plots with a mixture of CaO and urea, at rates of 5 t/ha and 200 kg N/ha respectively, by incorporation to a depth of 30 cm. Populations of *P. solanacearum* were then monitored over a 6-month period during which time the plots were manually weeded. One month following a second amendment at the same rates, 4-week-old tomato seedlings (cv. Marglobe) were transplanted into each plot (40 plants/plot) and the incidence of bacterial wilt was recorded over time and compared to that in nonamended plots which had undergone the same weeded-fallow treatment.

The effect of nitrogen fertilisation on the interaction between susceptible tomato seedlings (cv. Moneymaker) and biovar 1 strain of *P. solanacearum* strain (K-60) was studied using a modification of the in vitro pathogenicity test of Boucher et al. (1985). Two-week-old tomato seedlings, grown axenically on vermiculite containing nutrient solutions with varying concentrations of either KNO_3 or NH_4NO_3 (at 0, 16.8 or 33.6 mM), were inoculated in culture tubes with 1 mL of a suspension containing 1×10^8 cfu of the pathogen. Disease incidence (at 30°C and 13000 lux) was then recorded over a 7-week period.

The combined effect of maize rotation, weed control and soil amendment on the level of bacterial wilt in a subsequent potato crop was determined during the 1989–90 season. Immediately after harvest of a highly-infected potato crop, an area 1800 m^2 was prepared and divided into two halves. In one half a 6-month maize crop was grown whereas the other half was left fallow. Soil was amended with CaO and urea (as before) before planting of maize and again immediately after harvest, whereas the soil in the fallow area was not amended. Weed control in the maize crop was by one application of 2,4-D after planting of the maize and one application of metribuzin after harvest. Weed control was not applied in the fallow area. Soilborne populations of *P. solanacearum* were monitored during the rotation period as described above. Following harvest of the maize, pathogen-free seed-potato tubers were planted in plots (60 plants in 12 m^2/plot) in randomised blocks with five replications. Disease incidence in susceptible cultivars (LT-1, LT-2 and LT-5) and a resistant cultivar (BR-69.84) was recorded at intervals during the season.

Results

In both seasons, the population of *P. solanacearum* in maize rhizosphere soil samples declined to below detectable levels more rapidly than in soil taken from the herbicide-treated fallow or the fallow containing natural weed populations (Fig. 1). In the 1989–90 season, soil from weed rhizospheres remained highly infested throughout the rotation period and this was associated with the presence of high populations of the pathogen in roots of the weed *Eleusine indica* (mean $\log_{10}$ cfu/g root = 3.581±0.618). Colonisation of weed roots was not detected during the 1988–89 season when the pathogen population eventually declined below detectable levels even in the weed-infested fallow. *E. indica* did not colonise fallow plots in this season. When the bacterial content of maize roots was examined, *P. solanacearum* was not detected in either year but high populations of another bacterium were always recorded on the selective medium (mean $\log_{10}$ cfu/g root = 6.999±0.256). This bacterium was later characterised as *Pseudomonas cepacia* according to the cellular fatty acid profile (determined by D.E. Stead, Ministry of Agriculture, Fisheries and Food, Central Science Laboratory, Hatching Green, Harpenden, AL5 2BD, U.K.) and was antagonistic to *P. solanacearum* on both King's B medium and potato dextrose agar. Populations of *P. cepacia* in weed rhizospheres or in herbicide-treated soil were significantly lower than those in soil from around maize roots (Table 1) suggesting a possible association between the multiplication of the antagonist and the decline of *P. solanacearum* populations in the maize rhizosphere.

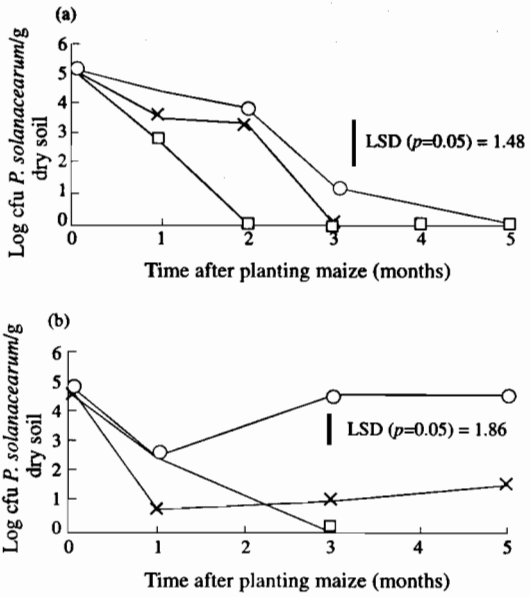

Fig. 1. Effect of short rotation treatments on soilborne populations of *Pseudomonas solanacearum* in (a) the 1988–89 and (b) the 1989–90 growing seasons. Maize —□—; fallow + herbicide —×—; and fallow + weeds —○—.

Soilborne populations of *P. solanacearum* were clearly affected by the rotation treatment but the effect on bacterial wilt incidence in the following susceptible tomato crop was less obvious (Fig. 2). Although pathogen populations fell below detectable levels after maize, the residual inoculum density was sufficient to induce disease in both years. The rate of disease development was lower in both years following maize or herbicide-treated fallow than following weed-infested fallow, reflecting probable differences in inoculum potential in the soil after the rotation treatments.

In the 1988–89 season, the incidence of bacterial wilt after maize eventually reached similar levels to the weed-infested control, whereas it remained significantly lower in the 1989–90 season. Following the herbicide-treated fallow, however, the level of disease remained lower than the control in both seasons. These differences were attributed to damage of the tomato indicator plants by the root-knot nematode during the 1988–89 season (Table 2) which did not occur during the following season. Only trace levels of nematode damage were detected following the herbicide-treated fallow, indicating that the *Meloidogyne* spp. did not survive the rotation period in the absence of host plants.

Soil amendment with either calcium oxide or urea significantly controlled bacterial wilt following the

inoculation of potato seedlings under screenhouse conditions (Table 3). Less drastic, but significant, effects were also observed under field conditions in both seasons (Fig. 3). In 1988, 1 month after incorporation of the mixture of CaO and urea, the populations of *P. solanacearum* in the soil of amended and nonamended field plots did not differ significantly ($\log_{10}$ cfu/g dry soil = 3.839±0.839 and 3.687±0.841, respectively). Similarly, soilborne populations of the pathogen did not vary significantly between amended and nonamended soil when monitored the following year (Fig. 4). Further experimentation, under sterile in vitro conditions, showed that the incidence and severity of bacterial wilt was reduced in hydroponically-grown tomato seedlings when the levels of KNO_3 or NH_4NO_3 in the nutrient solution were increased prior to inoculation with *P. solanacearum* (Fig 5).

The additive effects of maize rotation, herbicide treatment and soil amendment on soilborne populations of *P. solanacearum* were not greater than the effects of maize rotation alone (Figs. 1 and 6). However, the

(1985).Nutrient amendment -O-=none; -□-= KNO_3 (16.8 mM); -●-=NH_4NO_3 (16.8 mM); -X- = KNO_3 (33.6 mM); and -▲- =NH_4NO_3 (33.6mM).

combined effects of the control measures on the reduction of bacterial wilt in the subsequent potato crop were highly significant (Fig. 7). The degree of control was also influenced by the cultivar of potato grown. All cultivars showed tuber infection at harvest although this was reduced by the integrated control measures (Table 4). The yield of healthy tubers was higher in the susceptible (but heat-tolerant) cultivars than in the resistant (but non-adapted) cultivar, and yield was significantly higher in plots where the integrated control measures were applied.

Discussion

The rate of decline of populations of *P. solanacearum* in field soil following a highly infected potato crop was clearly affected by the rotation treatment and cultural practices employed afterwards. However, the method used to detect bacterial populations in soil was insufficiently sensitive to reliably study the relationship between residual pathogen populations in the soil after rotation treatment and the incidence of bacterial wilt in the subsequent susceptible crop. It was obvious that, even where the bacterium could not be detected, the residual pathogen population after one rotation period was sufficient to initiate disease. The sensitivity of detection was probably limited both by the sampling procedure used and by the suppression of growth of *P. solanacearum* by high populations of saprophytic bacteria which also grew on the selective medium. Furthermore, factors other than the initial inoculum density of *P. solanacearum*, i.e. density and distribution of root-knot nematodes and antagonistic bacteria (e.g. *P. cepacia*), as well as the levels of urea and CaO used, influenced disease development. Use of the selective medium in the development of disease-forecasting procedures was therefore considered inappropriate.

The role of *P. cepacia* and other interacting soilborne organisms in the suppression of *P. solanacearum* during crop rotation demands further study. *P. cepacia* was commonly isolated from maize roots in high populations in both seasons, both from the experimental sites and from farmers' fields in the surrounding area. Furthermore, cultures from maize roots on the selective medium were usually devoid of other saprophytes which were commonly isolated in cultures from soil or roots of other plants. The presence of this or similar bacteria in maize roots may help to explain the control of bacterial wilt in potato intercropped with maize (Autrique and Potts 1987).

The interaction between *P. solanacearum* and *Meloidogyne* spp. has been well documented (Jatala et al. 1988). In general, root damage by the nematode facilitates infection by the bacterium and aids disease development. As a result the inoculum potential of *P. solanacearum* required to induce disease is much lower when the nematode is present. Since both organisms often occur together in tropical soils, it follows that any cropping system designed to combat bacterial wilt must also be effective against root-knot nematode.

Similar results on the effects of single rotations on potato bacterial wilt caused by race 1 were obtained in Costa Rica by Jackson and Gonzalez (1981); herbicide treatments provided some control while single rotations

with non-host crops did not affect disease development. Nevertheless, sufficient evidence has been accumulated here to show the value of single rotation crops in an integrated control system. The choice of crop (and cultivar) will be location specific, depending on resistance to infection of the crop itself by local strains, as well as its effect on populations of nematodes, antagonistic bacteria and other interacting organisms. Long-term crop rotation for smallholder farmers is not a practical solution since land is not available. The alternative is therefore to simultaneously apply complementary crop protection measures to suppress pathogen populations as much as possible in the time allowed. Liming, urea application and weed control (whether chemical or manual) are common practices which can be readily adapted to most farming systems.

In Taiwan (Chang and Hsu 1988; Hsu and Chang 1989), control of bacterial wilt by soil amendments containing urea and CaO, as well as other organic and inorganic components, has been associated with indirect effects on the activity of other soilborne microorganisms which influence the survival of *P. solanacearum* in the soil. In the French West Indies (Prior and Beramis 1990), it was suggested that high applications of urea increased host resistance to bacterial wilt. The results presented here confirm that the soil amendments can reduce bacterial wilt incidence. Control through increased nitrogen fertilisation occurred in the absence of microorganisms other than the pathogen. Furthermore, inoculum potential was not significantly affected by soil amendment under field conditions. It would therefore seem that mechanisms other than the influence of antagonists on *P. solanacearum* populations were involved in this case. Further research is planned to determine the effects of amendments on host resistance and pathogenicity, aggressiveness or growth rate of the pathogen.

Although integrated control of bacterial wilt was demonstrated, disease incidence was generally high by the end of the growing period and yields were correspondingly low, even in treated plots. This was partly a result of the deliberate choice of high and uniform inoculum potential at the experimental sites and the highly conducive climatic conditions for bacterial wilt development. Also, rapid and extensive spread of infection from diseased to healthy indicator plants within the small experimental plots meant that final disease incidence was not a reliable indication of differences in inoculum potential which resulted from the application of control measures. Better levels of control could be expected in farmers' fields, with natural levels of inoculum, larger experimental areas and more suitable growing conditions for the potato. Furthermore, since crop rotation and the removal of weeds and groundkeepers are usually more effective at controlling the host-specific race 3 of *P. solanacearum* than the non-specific race 1 (French 1988), higher levels of control may be anticipated in race-3-infested areas than were observed with race 1.

The choice of potato cultivar is clearly an important factor in the success of an integrated control strategy. Although the cultivar BR-69.84, having resistance genes from *Solanum phureja*, was least affected by the disease, it was not adapted and yielded poorly. Genes for both adaptation to the environment and resistance to the disease are required for the adequate expression of resistance in potato (Tung et al. 1990). Conversely, the other cultivars, although well adapted, lacked sufficient resistance to escape the disease, although some responded better to the integrated control measures than others. All cultivars produced infected tubers which would be unsuitable for use as seed the following year. It should therefore be stressed that sustainable potato production under such conditions would rely on the constant availability of pathogen-free planting materials from elsewhere.

Only when potato cultivars are developed with high levels of resistance to both bacterial wilt and tuber latent infection, as well as resistance to other important diseases, good adaptation to the environment and acceptable agronomic and cooking quality, will their potential in strategies for the control of bacterial wilt be fully realised. Currently available cultivars with tolerance to the pathogen (Schmiediche 1986) could be utilised in combination with complementary control measures that maintain inoculum pressure below a critical threshold and/or minimise stress on the plant. However, most of these cultivars permit pathogen multiplication and movement within the plant and tubers while remaining asymptomatic, and therefore can maintain inoculum density as well as act as symptomless carriers of the pathogen (Granada 1988). It may therefore be more advisable to select susceptible but adapted cultivars (such as LT-5 in this case) which respond well under local conditions to the integrated control strategy, yield well and which show symptoms when infected (and can therefore be identified and eradicated).

Integrated Control of Bacterial Wilt in Seed Production by the Burundi National Potato Program

D. Berrios M. and A. Rubirigi*

Abstract

One of the major biotic constraints to potato production in Burundi is bacterial wilt (race 3) which may reduce yields by 30–50%. Latent infection was a serious problem making it almost impossible to produce disease-free seed. From seeds produced above 2250 m above sea level, diseased plants were observed only when they were grown at lower elevations. Because of this, and the associated poor cultural practices, significant yield reductions at lower elevations occurred. To overcome this problem, the Burundi National Potato Program (BNPP) adopted a program to produce high-quality basic seed of improved varieties and to develop appropriate methods for seed production in rural areas. The program has developed and used different technologies, particularly for improved seed production, which has resulted in a reduction of bacterial wilt infection from 60–0.7%. The system referred to as flush-out involves continuous replacement of planting material. The integrated system for production of clean seed in BNPP consists of a strictly one-way flow starting with a disease-free source of plantlets. This integrated system has been tested and adapted by other national programs in Central Africa, especially for use in seed farms for improved seed production.

BURUNDI is a small (27 834 km^2) Central African country struggling to achieve economic development. Its population is 5.5 million and growing, so with increasing food requirements, Burundi faces a mounting challenge to raise productivity on the massive number of small farms that constitute the backbone of the largely agrarian economy.

Greater productivity and more intensive use of available farmland are essential to meet the mushrooming demand for basic staples, as well as to improve rural income and thereby stimulate the growth of non-agricultural activities.

Agricultural planners are aware of the potential of the potato crop to contribute to economic development. Potato cropping was introduced to Burundi at the end of 19th century and was considered an 'exotic' crop for many decades until Institut des Sciences Agronomiques du Burundi (ISABU), with the technical support of the International Potato Center (CIP), established the ISABU National Potato Program in 1979 with the objective of promoting potato production.

*Institut des Sciences Agronomiques du Burindi, B.P. 75 Bujumbura, Burundi, Africa.

Prior to CIP's involvement, all potatoes grown in Burundi were of European origin. They were highly susceptible to late blight and bacterial wilt, the two major constraints to potato production in the country (Autrique and Perreaux 1989). Other main constraints were the lack of appropriate agronomic technologies and the absence of sufficient quantities of pathogen-free, high-quality seed (Devaux and Bicamumpaka 1984).

Bacterial wilt caused by *Pseudomonas solanacearum* race 3 is the most common pathogen found in Burundi (Autrique and Potts 1987), particularly in the moderately cool highlands. Race 3 dissemination occurs through latent infection and the persistence of the pathogen in the soil. This disease is considered one of the limiting factors to potato production in the tropics. Most commercial varieties are very susceptible, especially when grown at field temperatures above 28°C.

The primary objectives of research in the potato program were to explore the possibilities of controlling bacterial wilt by producing high-quality basic seeds of improved varieties, developing appropriate methods for seed production in rural areas and improving

cultural practices and testing technologies to increase potato production.

Potato Program of ISABU

The potato program of ISABU has three experimental stations for seed potato production. Gisozi (headquarters) is located at 2050 m above sea level, has a good in vitro laboratory for maintenance and multiplication of disease-free material, and four screenhouse facilities for producing tubers of in vitro material. Munanira is 2150 m above sea level and is used for pre-basic seed production (1.5 ha/season). Mwokora is 2250 m above sea level and is used for basic seed production (8–10 ha/season).

The two rainy seasons occur from September–January and from February–June permitting potato growing in the hills. There is a third short dry season from June–August when potatoes are planted in the swamps (marais).

Production of Clean Seed

In vitro plantlets from CIP, Lima are multiplied in the laboratory in Gisozi. After 2 or 3 in vitro multiplications, plantlets are transplanted to pots, bags or beds in the screenhouse. After 3–4 weeks the rapid multiplication program starts. The first cuttings are taken when the plants have 5–6 simple leaves. Each mother plant can be harvested 2–8 times according to the variety, growing conditions, etc. Each harvest is greater than the first. Cuttings are taken at 15–20 day intervals for a period of about 100–120 days. Other techniques such as sprout cuttings, stem cuttings, top shoot cuttings and in vitro plantlets transplanted directly in the beds are also carried out. Since varieties react differently to propagation, the aim is to find the best and the most economical technique.

Tubers from in vitro plants multiplied at Gisozi are used to plant 1.5 ha/season in Munanira. The next step is to plant 8–10 ha/season at the Mwokora basic seed farm, using material from Munanira and smaller amounts of material from positive selection. Seven clones have been released and named as varieties for seed production in the BNPP (Table 1). Potato seed produced at Mwokora is supplied to the National Seed Service (NSS), and Regional Development Projects (RDP) are responsible for further multiplication and seed distribution.

The RDPs follow the methods developed by the program in setting-up their own seed farms (Fig. 1). Coupled with good cultural practices, roguing of the crop, rotation with forage crops, improved seed storage and careful distribution, the new 'healthy material' has significantly reduced bacterial wilt and increased seed quality.

The improved seed stock has reduced the occurrence of bacterial wilt in ISABU seed farms from 64.1% in 1986 to less than 1% in 1991, while the basic seed production has increased from 105.2 t in 1985 to 377.5 t in 1991 (Table 2). Also, the incidence of bacterial wilt

1990	68.8	0.7	295.6	0.9
1991	72.5	0.5	377.5	0.7

[a]2150 m above sea level, 1–1.5 ha /season with in vitro material since 1989 (pre-basic-seed)
[b]2200 m above sea level, 8–10 ha/season planting, material coming from Munanira and S+(basic seeds)
[c]Total yield/year (total production for seed distribution).

has remained at levels below 3% in the three main Burundi Regional Development Projects for potato seed multiplication (Kajondi, Cvha and Bututsi). As bacterial wilt has been controlled so production has increased (Fig. 2).

Pre-basic and basic seed production and percentage of bacterial wilt from 1988–1991 were compared (Table 3). Negative selection (S-), positive selection (S+) and in vitro material, all affected the amount of 'healthy seed' and contributed to reduced infection levels.

The variety Ndinamagara (Cruza-148) grows well under laboratory conditions (in vitro) and all the basic seed produced in Mwokora comes from second generation in vitro, but Uganda 11 variety has some problems of growth in solid Murashige and Skoog medium under Burundi laboratory conditions, and its multiplication is less than Ndinamagara. The behaviour and the rate of multiplication of other varieties is good.

Seed source trials confirmed that using good quality seeds results in less wilt. Trials using two seed sources from Munanira 2nd or 3rd in vitro generation and Mwokora 4th or 5th generation, were compared to determine the best seed source at ISABU Mahwa station, located in the Bututsi Region which is warm and of medium elevation. Four potato varieties—Ndinamagara, Sangema, Uganda 11 and Lupita—were also tested. The results showed that the Munanira source was the best. On the four varieties tested, the percentages of wilted plants (WP) were, respectively, from Munanira station 0, 2.5, 1.5, and 1.0 and, from Mwokora station, 0, 10.5, 87.5 and 4.5. Similar results occurred when the assessment was for total percentage of wilting plants (TBW). It is important to note that there was a high percentage of WP in Uganda 11 from Mwokora after several multiplications and high yield losses also occurred. This was probably caused by latent infection; it did not occur in the other varieties (Fig. 3).

On-farm research has been an integral part of the development process. The program has adopted a philosophy approximating to the 'farmer back to farmer' model; that is, continuous involvement of the farmer and the use of on-farm research at all stages of development of a technique, variety, etc. Studies were conducted to assess the impact of improved technologies on incidence of bacterial wilt in farmers' fields. In general the trend was for an increase in yield per plant and a decline in bacterial wilt as the seasons progressed (Table 4).

The differences in yield and bacterial wilt were gradually noted by the farmers and during the first 1990 season they decided to implement only the improved agronomic practices.

Conclusions

The full potential of potato as a food crop in Burundi has yet to be realised. Its short vegetative cycle, high production of calories per hectare per day, and its widely appreciated taste and favourable price, all indicate that potatoes are a crop that growers would like to produce more extensively. A national program of potato research and development is now in place and produces basic planting material. Improvements at the level of the rural development project would help increase the supply of improved quality seed available to growers in many cases.

Race 3 of *Pseudomonas solanacearum* is the cause of bacterial wilt of potato in Burundi (Autrique and Potts 1987; Autrique and Perreaux 1989), and *Solanum tuberosum* is the major host plant. The main sources of infection are contaminated seeds and infested soil, and rotations can reduce bacterial wilt inoculum in the soil. A series of trials has been conducted since 1987 that include potato in rotation with natural fallow, herbicide-treated soil, buckwheat, maize, wheat, *Setaria* sp., peas and beans. Results have shown that cereals such as wheat or *Setaria* sp., can reduce wilt incidence when planted separately and after potato. The dry season can reduce the wilt inoculum in soil on well prepared and clean land.

Disease Management Strategies for the Control of Bacterial Wilt Disease of Potato in Mauritius

S. Saumtally, L.J.C. Autrey, P. Ferré and A. Dookun*

Abstract

Bacterial wilt caused by *Pseudomonas solanacearum* is the most serious disease of potato in Mauritius and is a major constraint to production. Race 1, biovar 3 is the only race of the pathogen identified and is present in most cultivated soils of the island. An integrated approach was developed to manage the disease and has proved very successful in reducing wilt. Before release for commercial plantations, varieties are screened to the pathogen in infested soil and by an infectivity titration method. Planting in the cool season, long crop rotation in sugarcane interrows, clean seed and cool storage of seeds are standard practices used to control the disease. The population of the bacterium in tubers decreases markedly after storage for six months at 2–4°C. Soil solarisation and soil amendments are being investigated as control measures to reduce levels of soilborne inoculum. Diagnosis of the bacterium in seed and soil by immunofluorescence, ELISA, NCM-ELISA, use of selective media and bioassay methods is also being investigated. More advanced diagnostic techniques using monoclonal antibodies, DNA probes and PCR have also been acquired. Clones adapted to lowland tropical conditions and resistant to bacterial wilt are being developed in a joint Mauritius Sugar Industry Research Institute–International Potato Center project.

In Mauritius, 77% of potato production is planted in sugarcane interrows and the association of these two crops has proved to be very successful as neither of their yields is reduced (Govinden 1990). In the 1970s a seed-potato program for local production was launched and the scheme has evolved successfully in the light of experience acquired over the years through production under lowland tropical conditions (Autrey et al. 1991). Thus, seed production has increased from 864 tonnes in 1979 to 1768 tonnes in 1991, the latter representing 75% of local requirements. Bacterial wilt caused by *Pseudomonas solanacearum* is one of the diseases that the scheme has to account for. The pathogen occurs in most of the cultivated soils of Mauritius and characterisation of isolates has shown that race 1, biovar 3 is present (Lallmohamed 1976). Since race 1 is soilborne and has a wide host range (Bradbury 1986), its control is difficult and the disease is one of the main constraints to both seed and market potato production. As no single control measure is adequate (French 1988), an integrated approach has been adopted to reduce the impact of the disease. Details of this strategy, its effectiveness and likely future developments are reported in this paper.

*Mauritius Sugar Industry Research Institute, Réduit, Mauritius.

Evaluation of Clones to Bacterial Wilt

Field

Potato varieties from Europe and the International Potato Center (CIP) were evaluated in the field under irrigated condition from March to June in the northern subhumid region of the island (altitude 80 m; 20–29°C). The trials were established in a low humic latosol soil type, in plots known to be infested by the bacterium. Before planting, a susceptible tomato variety was sown to build up the inoculum. Nevertheless, due to uneven distribution of inoculum in the

soil, clones sometimes escaped infection and required further testing or confirmation of their rating the following year. Table 1 shows the reaction of 12 varieties that have been exposed to bacterial wilt at least twice. It must be emphasised that not all susceptible clones are rejected: some are grown commercially to satisfy consumer preference. However, the acquisition of a resistant or tolerant clone may allow production to be sustained in regions such as the eastern sector of the island recognised to be conducive to bacterial wilt infection and where potatoes cannot be grown at present.

Glasshouse

Clones at the final stage of selection are further tested by an infectivity titration method. This involves the preparation of bacterial concentrations of *P. solanacearum* by serial dilutions from 1×10^9 cells/mL to 1×10^1 cells/mL. A given volume of suspension is used to inoculate a known weight of soil. The final numbers of bacteria per gram of soil are calculated. A range of concentrations from 4×10^2 to 4×10^7 cells/g of soil was found adequate for evaluating clones. The inoculum is applied to the soil by knapsack sprayer and the soil thoroughly mixed before filling plastic pots. Twenty tuber units per clone are tested for each concentration, uninoculated soil being included as a control.

Typical results obtained with varieties Up-to-date (susceptible), Spunta (intermediate) and BR 63-76 (resistant) are given in Table 2. A concentration of 4×10^2 cells/g of soil was sufficient to induce wilt in variety Up-to-date, whereas 4×10^5 cells/g of soil was needed for Spunta. A much higher threshold (4×10^7 cells/g) was required for the CIP clone BR 63-76. These results agree with field observations on the disease resistance of these three varieties.

The threshold level for wilt induction will vary with environmental conditions, particularly temperature and humidity.

Table 2. Bacterial wilt percentage induced by different inoculum dosages in three varieties of potatoes.

No. of bacterial cells/g of soil	Up-to-date	Spunta (% wilt)	BR 63-76
4×10^1	0	0	0
4×10^2	5	0	0
4×10^3	20	0	0
4×10^4	35	0	0
4×10^5	45	15	0
4×10^6	55	50	0
4×10^7	65	55	5
Uninoculated	0	0	0

Cool Season Planting

The planting period in Mauritius is divided into first and second seasons and starts in mid-April. It is recommended that harvest be completed by mid-November, before the summer rains. During the period of cultivation, mean temperatures vary from 20.5–24.7°C in the north, 20.3–23.6°C in the south, 19.7–23.9°C in the east, 21.3–25.9°C in the west, and 17.3–21.7°C in the central region.

The relatively cool weather and light precipitation do not favour wilt development, although the disease is still present. In certain years, heavy rainfall extending into the first season in May, or a combination of high rainfall and heat at the end of the second season in December, causes an upsurge in the incidence of bacterial wilt, resulting in financial losses due to poor yields and rejection of seed fields. This leads to a need to import both seed and market potatoes. Nevertheless, planting during the cool season greatly mitigates the effects of the disease.

Determination of Wilt Potential of Soil

Soil from fields to be planted with potatoes was bioassayed to determine its wilt potential (Félix and Ricaud 1978). Soil was collected at a depth of 10–30 cm, thoroughly mixed and placed in pots of diameter 27 cm and height 33 cm. These were left to stand in $82 \times 62 \times 8$ cm high trays completely filled with water so that the water content of the soil ranged from field capacity at the top to saturation at the bottom. A minimum of 50 samples/ha is recommended. Tomato seeds of the highly susceptible variety Marglobe are sown in the pots. Sterilised and naturally infested soils are included as controls.

In heavily infested soil, wilt incidence is high and occurs early (within 15 days) whereas in soils with lower inoculum levels, wilting is not only reduced, but also the appearance of the disease is delayed (up to 70 days). While the bioassay method gives a good

indication of the wilt potential of a field, it suffers from the following disadvantages: (i) it is lengthy and cumber-some, requiring a sheltered area and large numbers of pots and trays; (ii) only a few samples per field are taken as they are bulky, with the consequence that the bacterium may escape detection; and (iii) the appearance of symptoms is delayed in moderately infected soil, resulting in field management problems if alternative fields have to be looked for. Other methods are currently being investigated.

Crop Rotation and Weed Control

Seed and market potato production is mainly in the interrows of sugarcane at replanting or in rotational lands between two cane cycles. As each cycle lasts 7–10 years, potato is planted in the same field only after that period. Reports on the persistence of *P. solanacearum* in soil vary and depend on several interacting factors such as strain, environmental conditions and soil type, but in general,a 2–5-year rotation with non-host species is effective (He 1990). In Mauritius, though the bacterium could survive in host weeds, the extent of survival is apparently low because of good herbicide-based weed control practices by growers. The severity of the disease has been shown to be reduced in potato when weeds are eliminated by herbicide treatments (Jackson and Gonzalez 1981). Lining interrows of sugarcane is also effective in reducing weeds. The long crop rotation period, combined with weed control, therefore contribute to the decline of bacterial wilt inoculum in the soil.

Soil Solarisation and Soil Amendments

Experimental trials are currently under way to determine the potential of soil solarisation and soil amendments for reducing the population of *P. solanacearum* in the soil.

Soil solarisation using clear plastic sheeting to cover moist soil for 6 weeks yielded only slight control. Unsolarised plots had 61% wilt compared with 54% in solarised plots. However, during the time the experiment was conducted, the differences in temperature between covered and uncovered plots were only 6.9, 6.0 and 5.4°C at 10, 20 and 30 cm depths respectively. Higher temperature differences attainable in the hottest summer months (December–February) may prove more effective. Modifications using a combination of transparent and dark plastic to achieve higher temperatures are currently being investigated.

Cool Storage of Seed

Harvested seed potatoes are stored at 2–4°C for at least 6 months at the Agricultural Marketing Board, the central storage facility. Storage under these conditions prolongs the dormancy period and maintains the physiological status of seeds. A study was conducted to investigate the effect of cool storage on the viability of *P. solanacearum*. Infected tubers were kept over a period of 1 year, samples taken at monthly intervals being incubated at 28°C for 3 weeks to induce proliferation of the bacterium (Gonzalez 1977) before plating on Kelman's tetrazolium chloride medium TZC (Kelman 1954). PLating material was collected by taking tissue cores at the stolon end after surface sterilisation with 70% ethanol and removing the epidermis (Janse 1988). The tissues from 10 tubers were finely sectioned, and allowed to diffuse in 1–2 mL sterile distilled water for 1 hour. Loopsful of the diffusate were then plated. The number of cells decreased rapidly after the first 4 months of storage to become undetectable after 6 months. Since this experiment was performed with heavily infected tubers, it seems that cool storage could play a role in the elimination of *P solanacearum* in latently infected tubers. Similar observations have been reported for *Erwinia carotovora* subsp. *carotovora* (Dookun and Autrey 1991).

Clean Seed

Seed potato is produced by experienced growers using basic or elite seed material from Europe and multiplied for only two generations before being sold to planters as certified seed (Autrey et al. 1991). Inspections for diseases are carried out during active growth. Fields with wilt infection are rejected or, in case of patchy infection, the infected parts are discarded. At harvest, 40 tuber units/tonne are sampled at random, dormancy broken and tubers planted in the glasshouse and under field conditions at two locations. If the performance-testing reveals the presence of diseases that are not within the set standards, the seed consignment is rejected.

This certification system has proved to be very efficient and has contributed greatly in providing clean planting material to growers. The status of bacterial wilt in these tests has been negligible.

The seed potato program is supported by tissue culture techniques. Micropropagation of promising clones and commercial varieties, coupled with indexing for diseases at all multiplication stages, are being successfully applied to the production of elite seed locally. A scheme has been established with the aim of producing 300 tonnes of two commercial varieties by 1996. Air-conditioned glasshouse and screenhouse facilities are available for bulking under ideal conditions. The seed certification scheme and in vitro micropropagation technique are important aspects in maintaining the healthy status of potato seed in Mauritius.

Development of Clones with Resistance to Bacterial Wilt

A collaborative project between the Mauritius Sugar Industry Research Institute (MSIRI) and CIP was initiated in 1989 to develop clones for cultivation under lowland tropical conditions. Progeny from 110 direct crosses were screened and 152 clones have been selected. Thirty-three of them were included in this year's bacterial wilt resistance trial but the results were inconclusive. They will be evaluated again in 1993, along with the remaining clones.

Detection

Since *P. solanacearum* is very often present as latent infection in potato (Granada 1988) detection of the bacterium in seed is of great importance. Detection in seed and quantification of the bacterium in soil deserve equal attention since plantation of clean seed in infested soil defeats the purpose. Both specific and sensitive techniques are required for reliable detection of *P. solanacearum*. The techniques must, however, be easy to perform so as to enable handling of a large number of samples. The following methods were investigated: indirect immunofluorescence, ELISA, NCM-ELISA, and plating on semi-selective media.

Detection in soil

Five gram quantities of soil, sterilised and non-sterilised, were artificially infested with the bacterial wilt organism so that a range of concentrations from 1×10^1 to 1×10^8 cells/g of soil was achieved. After 3 weeks incubation at 28°C, the bacterium was extracted by shaking the soil with 5 mL sterile distilled water and allowing it to stand for 2 hours. The diffusate was then used for the following tests: 10 µL spotted on an immunofluorescence slide; 5 µL spotted on nitrocellulose membrane; 50 µL diluted in 50 µL of coating buffer for indirect ELISA; and 10 µL spread plated on semi-selective media. Three media were compared: TZC; Granada and Sequeira medium (Granada and Sequeira 1983) as modified by Tsai et al. (1985) and CIP (TZC supplemented with 50 ppm crystal violet and 100 ppm polymyxin B sulphate). The bacterium could not be detected by any of the serological methods from non-sterile soil. In contrast, *P. solanacearum* could be isolated on all three media when present initially at 10^6 cells/g of soil. The two tetrazolium media supplemented with antibiotics were by far superior to TZC as the number of contaminants was reduced by 10 times in both of them. Although the bacterium could be isolated on TZC, the recovery rate on the modified medium of Tsai et al. (1985) was increased twice while on the CIP-modified medium the number of *P. solanacearum* colonies was four times greater than on the TZC medium. This test has also proven conclusive with naturally infested soil.

With sterilised soil, it was observed that the bacterium could be detected by all four methods even at the lowest dilution. This could be explained by the proliferation of *P. solanacearum* in the sterilised soil, being free of competition and antagonists. It is proposed to use the isolation method for the detection of the bacterium in soil. The use of an extraction buffer is being evaluated for extraction of *P. solanacearum* from soil (Forde and Robinson 1992).

Detection in seed

Detection of latent infection of *P. solanacearum* in potato seed was investigated using the same techniques as for detection in soil. Tissues were treated as described previously using the stolon end of the tuber. After maceration of tissues and diffusion in sterile distilled water, the diffusates were treated as for detection in soil. All four of the techniques detected latent infection of *P. solanacearum* in tubers.

Conclusion

In Mauritius, a wide range of measures has been adopted for the control of bacterial wilt. Resistant or tolerant varieties are recommended, although consumer acceptance of the product is a major determinant. Clean seed is used and multiplication over a few generations ensures that good quality planting material is available. Long rotations coupled with the use of herbicides and roguing of infected fields favour the decline of the population of *P. solanacearum* in the soil. Moreover, growers are encouraged to use a bioassay method to determine the wilt potential of the soil before planting a field with potato. Cool-season planting is also unfavourable for wilt development and storage of seed at 2–4°C helps to eliminate latent infection. These strategies have proved to be effective in reducing the impact of the disease. However, further research is required to ensure better control of *P. solanacearum*. A significant step forward would be the selection of a resistant variety through the MSIRI–CIP collaborative potato-breeding project. Future research in Mauritius will focus on the feasibility of soil solarisation and soil amendments, as well as the application of antagonistic agents for the control of bacterial wilt in the soil. More sensitive detection methods are also being investigated. Technologies for monoclonal antibody production, polymerase chain reaction (PCR) and DNA probes are already available and are being applied against other plant pathogens. Primers for PCR and DNA probes for the detection of *P. solanacearum* have already been developed by other

laboratories and could be tested under field conditions if made available.

Acknowledgment

The authors are thankful to Dr C. Ricaud, Director, MSIRI for his valuable suggestions in the preparation of the manuscript and permission to publish.

Contribution to Integrated Control Against Bacterial Wilt in Different Pedoclimatic Situations: Guadeloupe Experience

P. Prior*, M. Beramis*, M. Clairon, H. Quiquampoix†, M. Robert† and J. Schmit§**

Abstract

The severity of bacterial wilt (BW) has been reported to vary with environmental conditions, including the soil environment. In Guadeloupe, the control of BW in two contrasting soil types was attempted by management of water in irrigated vertisols and supply of organic amendments in oxisol soils. In the latter, large nitrogen inputs (ca. 750 nitrogen units ha/crop) greatly reduced the severity of bacterial wilt throughout several successive tomato crops. Among several inexpensive sources of nitrogen assayed, the organic forms, particularly sewage sludges, consistently proved more efficient than mineral ones. No correlation was observed between the reduction of BW and the fluctuations of several nitrogen-related members of the microflora or potentially antagonistic soil populations. The positive effect of nitrogen amendments presumably results from changes in host metabolism. In contrast to oxisol soils, most Guadeloupe vertisols have natural suppressiveness, mainly of physicochemical origin. Possible alterations of this property have been investigated with special attention to inoculum level and role of water on soil microporosity. Suppressiveness is markedly altered in conditions of high inoculum densities (above 5×10^7 bacteria/g dry soil) and excess of water. Minimal guidelines for water management of these irrigated vertisols have been defined to maintain their effective natural suppressive properties. These results, although some have local specificity, enhanced control measures and contributed to integrated control strategies against BW.

PSEUDOMONAS solanacearum E.F. Smith, the causal agent of bacterial wilt, severely affects solanaceous crops throughout the tropical belt. It has long been recorded as a soilborne, vascular pathogen, that demonstrates a wide variability in its host range, geographic spread and telluric survival (Buddenhagen and Kelman 1964; Hayward 1991; Kelman 1953). The occurrence of wilt seems to vary according to climatic conditions, cropping practices, and telluric environ-ment. The pathogen survives in soils and in the rhizosphere of numerous solanaceous as well as non-solanaceous plants (Granada and Sequeira 1983; Quimio and Chan 1979). In Guadeloupe (French West Indies), the susceptible crops are primarily tomato and eggplant. Strains were reported to be race 1 (Digat 1968; Prior and Steva 1990), which have been shown to survive longer in soils than others races (Moffett et al. 1983; Ramos 1976). Two main pedoclimatic situations in Guadeloupe are due to differences in the bedrock and the annual rainfall (Figs 1–2). One is prevalent in Basse-Terre, the humid mountainous island with oxisol soils where bacterial wilt is very severe. The other is widespread in Grande-Terre, the lower island, which has a drier climate with vertisol soils described as suppressive to bacterial wilt (Béreau and Messiaen 1975).

On a worldwide basis, the diversity of pedologic evolution. the variability of the pathogen and the diversity of crops and cropping practices throughout the tropics have prevented the application of a single strategy for control of bacterial wilt. However,

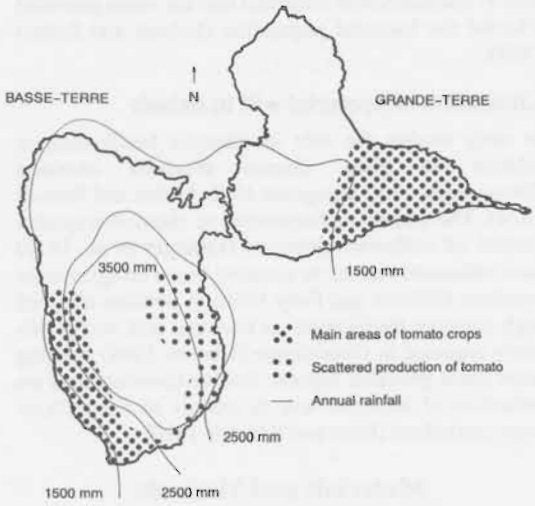

Fig. 2. Location of tomato crops and distribution of rainfall in Guadeloupe.

breeding for host resistance has been predominantly used and has provided substantial, although in some cases only temporary, success.

This paper deals with two experimental approaches that have been carried out either to investigate the suppressiveness of vertisols and outline their management or to reduce the incidence of bacterial wilt in the conducive oxisols. Both approaches are valuable components of an integrated control strategy.

Aspects of Guadeloupe vertisols

The suppressiveness of Guadeloupe vertisols has long been observed. Although the pH of the oxisols differs from that of the vertisols, this factor cannot entirely account for the suppressiveness (Berniac and Béramis 1973). Early investigations showed that suppressiveness was due to physicochemical characteristics of the main constituent clay (Béreau and Messiaen 1975; Messiaen et al. 1972; Rat 1978b).

Guadeloupe vertisols are characterised by a very high clay content (Table 1), almost exclusively composed of montmorillonite, a smectite clay (Colmet-Daage 1969; De Crécy 1969). A basic property of this clay family is the ability to swell with water uptake. Macroscopically, this causes the water clogging of vertisols in case of heavy rainfalls and the constriction of the clay matrix associated with shrinkage cracks when vertisols dry out. At the micrometric scale, swelling results from the plasticity of the typical tactoid network formed by smectite clays (Tessler 1984).

Table 1. Characteristics of clays from soils in Guadeloupe

Soils	Oxisols	Vertisols
Main clays	Halloysite and kaolinite	Montmorillonite
Locality	Basse-Terre (Domaine Duclos)	Grande-Terre (St-François)
Clay-content (%)	80–90	80–90
Cation exchange capacity (meq/100 g)	5–10	80–120
Total area (m^2/g)	10	750
Alkali saturation	Nonsaturated	Saturated
pH[a]	5–5.5	7–8
Organic matter content[b] (%)	2.7 (Horizon A) 2.7 (Horizon B)	3–4.5 (Horizon A) 1–2 (Horizon B; 80 cm)

[a]pH was recorded on samples dispersed in distilled water at concentrations of 1 and 10 mg of dry matter/mL.
[b]Measured on 10 mg of dried clays.

Studies on purified montmorillonite inoculated with *P. solanacearum* indicated that the water potential affected the bacterial population (Schmit and Robert 1984).

Limitation of bacterial wilt in oxisols

In early studies the role of nitrogen fertilisation in relation to plant disease received attention (Dommergues and Mangenot 1970; Huber and Watson 1974). The numerous limitations to chemotherapeutic control of soilborne pathogen (Enfinger et al. 1979) have enhanced interest in a control based on agronomic practices (Hoitink and Fahy 1986). A positive effect of high nitrogen fertilisation on bacterial wilt was previously reported in Guadeloupe (Clairon 1984) Starting from these previous reports, further investigations on reduction of bacterial wilt in oxisols of Basse-Terre were carried out (Prior and Béramis 1990).

Materials and Methods

Guadeloupe vertisols

Suspensions of virulent strains grown on Kelman's medium without TZC (Kelman 1954), were collected, washed and mixed into 2 g of clay extracted from vertisols by sedimentation (according to Stokes' law) to obtain a fluid paste. The final bacterial count was 10^{10} cells/g (dry clay), a number needed to increase the probability of viewing cells through the electron microscope, overcoming the problems of interference of the large surface area of these clays and the small area analysed by the electron beam (Schmit et al. 1990). The clay–bacteria samples were accurately equilibrated to a water potential of pF 2 (-10 KPa) with a pneumatic device previously described (Tessier and Berrier 1979).

Wilt incidence in vertisols as a function of inoculum

Seven bacterial suspensions, 200 mL each, were prepared by diluting a crude inoculum obtained from a 48-hour growth on Kelman's medium. The suspensions were adjusted to obtain final concentrations between 5.0×10^5 and 10^9 bacteria/g dry soil, after addition to oxic and vertic topsoils. For each concentration, bacterial suspensions were sprayed onto 12 kg of humid soil (corresponding to 8 kg of dry matter) and stirred in a concrete-mixer for 20 minutes with alternate directions every 5 minutes. A volume of sterile water similar to that of the suspensions was used as a control. Each mixture was equally distributed into six pots and immediately planted with five young plants per pot.

Inoculated soils were placed in a climatic chamber at 28°±3°C under 110 $\mu E/m^2/s$, 12-hour photoperiod, with 75–100% relative humidity. A foliar fertilizer was applied weekly. Wilted plants were recorded 21 days after planting. Isolations were made from wilted plants.

Limitation of bacterial wilt in oxisols

To monitor bacterial wilt in the experiments, a strain GT4-RN2 carrying a combined resistance to two antibiotics (nalidixic acid and rifampicin) was selected from a culture of a fluidal wild-type strain GT4 (race 1, biovar 3) of known virulence and aggressivity (Prior and Steva 1990; Prior et al. 1989). The pathogenicity and morphological stability of the double-resistant strain was checked.

Amended or non-amended (control) soil samples were inoculated with the resistant derivative from GT4-RN2. Final concentration in substrates was approximately 5×10^6 cfu/g dry soil which is close to the level of the resident bacterial flora (2.1×10^7 cfu/g dry soil).

Viable bacterial counts were routinely done on Kelman's medium (Kelman 1954) in modified form (Prior and Béramis 1990), from 40 g soil samples (wet weight).

Three forms of nitrogen supply were chosen, urea, soybean flour and sewage sludges, the last being used either in a raw form, as obtained from the purification station, or to evaluate the role of the flora brought with these sludges—sterilised three times before use. Amendments were based on 700 kg of nitrogen/ha for urea and 1400 kg/ha for the other amendments, assuming that only half of the organic nitrogen was directly metabolised. Oxisols from Basse-Terre whose main characteristics are summarised in Table 1 were sampled, limed (in the proportion of 1 t $CaCO_3$/ha) and divided in 10 equal lots before amendment and inoculation. Each lot was mixed with the corresponding amendments, inoculated in a concrete mixer and distributed in pots. Twelve days later, three tomatoes of highly susceptible cultivar Floradel with 3–4 developed leaves were planted in each pot. The plants were grown for 7 weeks under waterproof sheds. The unwilted plants were removed at the end of each crop, and the corresponding substrates separately rehomogenised and redistributed for the next crop. Three successive crops were raised.

The main microbial components of the flora (bacteria, actinomycetes and fungi) and the nitrogen-related populations (ammonifiers, nitrosifiers, nitrifiers, denitrifiers and proteolytics) were monitored every 10 days for each treatment. Twenty gram (wet weight) subsamples per pot were pooled, homogenised and 100 g were used for analysis according to the suspension–dilution and the most probable number methods (Pochon and Tardieux 1962).

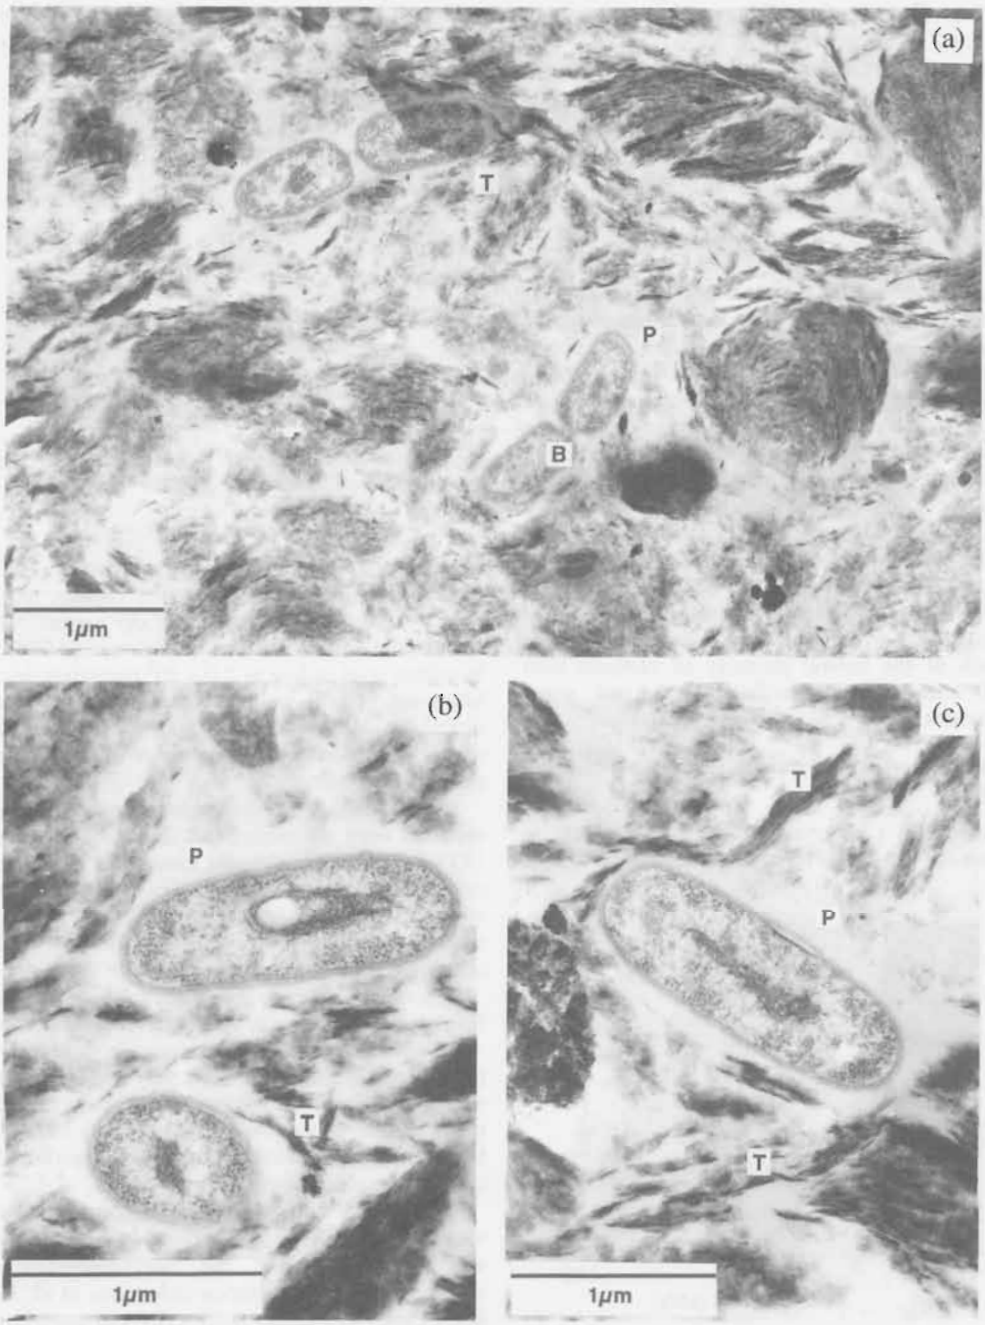

Fig. 3. Cells of *Pseudomonas solanacearum* observed in the porosity of native montmorillonite extracted from a Guadelope vertisol. Water potential of the sample:pF2 (–10kPa). (a) General view of bacterial cells (b) embedded in the clay matrix. (b–c) Individual cristallites of montmorillonite associate to form tactoids (T) delimiting pores (P) where bacteria are included. Tactoids are deformable and able to wrap around cells (c) or to come in contact at several points.

Results and Discussion

Guadeloupe vertisols

These studies enabled localisation of cells in pores and illustrated the embedding effect of tactoids close to bacteria (Fig. 3) with varying water contents (Schmit et al. 1990). The embedding properties of this deformable structure are effective even at moderately high water content like those found in the volume explored by roots.

If we assume that water in soil pores follows Laplace's law, we can delimit two domains where bacteria may live and multiply (Fig. 4). It can be postulated that cells are restricted in their passive movements when pore size decreases and/or when metabolites involved in the early stages of infection become trapped due to the high sorptive capacity of smectite clays, which subsequently reduces root infection. If availability of pore space is reduced when vertisols dry out, an excess of water could, in contrast, cause the pores to swell which would give the bacteria space to move and multiply. It may be postulated that breakdown in suppressiveness exists in over-hydrated field conditions. We therefore investigated a possible alteration of the natural property of vertisols with special attention to inoculum level and water management.

Wilt incidence in vertisols as a function of inoculum

Disease was not observed in vertisols with up to approximately 10^7 bacteria/g dry matter (Fig. 5),

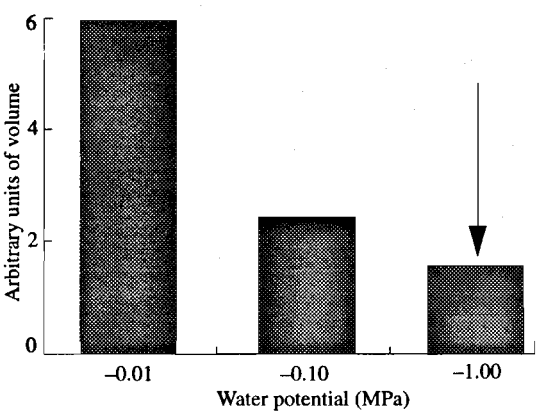

Fig. 4. Schematic representation of the theoretical volume of a vertisol at different water potentials. To the right of the arrow, the theoretical volume of pores (according to Laplace law) becomes smaller than the usual size of bacterial cells. Left of the arrow lies the domain where pore size in calcic smectite is bigger than usual volume of bacteria.

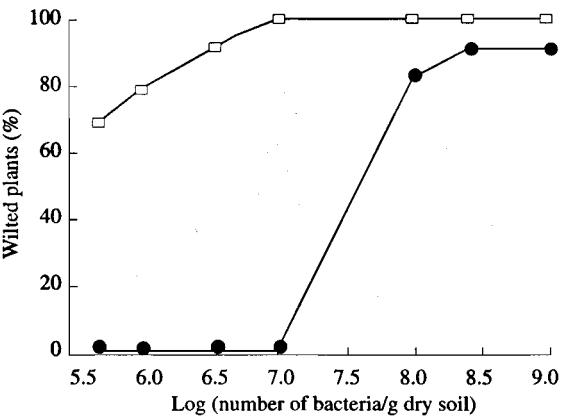

Fig. 5. Relationship between wilt incidence and inoculum level in an oxisol (□) and a vertisol (●).

whereas above this threshold, suppressiveness was reduced and the disease increased rapidly, reaching 90% wilt at about 10^8 bacteria/g dry vertisol. In the oxisols, used as a control, mortality reached 70% at an inoculum level as low as 5.0×10^5 bacteria/g dry soil. Moreover, 100% mortality was obtained for an inoculum concentration of 10^7 bacteria/g, a level which corresponded to an absence of symptoms on plants grown in vertisols.

The previous investigations on Guadeloupe vertisols were all carried out (Berniac and Béramis 1973) with inocula markedly lower than 10^7 bacteria/g dry soil, the limit shown in Figure 5. Suppressiveness was thus obtained below this threshold in various cropping conditions (greenhouses, fields), which is consistent with the results reported here.

It was noticed early that most soils suppressive to fungi were heavy soils with clay contents probably much lower than that of the vertisols described here (Toussoun 1975). In fact, their very high clay content makes these vertisols behave as pure clays. Thorough investigations on the role of clays (Stotzky 1972, 1980) have related their indirect effect to enhanced multiplication of bacterial antagonists.

If microbial antagonism occurs naturally in these vertisols in situ, they may play only a minor part in suppressiveness since the suppressiveness was maintained after sterilisation (Messiaen et al. 1972). Earlier and more recent studies (Béreau and Messiaen 1975; Messiaen et al. 1972; Prior 1990; Rat 1978b; Schmit and Robert 1984; Schmit et al. 1990;) support the view of a suppressiveness based primarily on a direct effect of the specific hydraulic and mechanical properties of smectite on bacteria, under pedoclimatic conditions including several dry periods each year.

On the basis of evidence of an inoculum limit and swelling properties of vertisols we postulated that suppressiveness could break down in over-irrigated conditions.

Since the beginning of an irrigation program that now covers most of the arable lands in Grande-Terre, field surveys and individual observations in irrigated vertisols have confirmed this (Bertrand et al. 1990). So far, bacterial wilt has been found occasionally in vertisols associated with an excess of water at the bottom of slopes and under overhead irrigation (Cabidoche and Ney 1986). When water management has followed agronomic recommendations, no wilt has been observed and expected yields have been obtained (Cabidoche and Ney 1986; Daly 1986.)

Unlike vertisols, oxisols in hill and lowland areas of Basse-Terre are conducive to *P. solanacearum*. Early observations (Rat 1978a) suggested that organic amendments could limit the incidence of the bacterial wilt in these soils which are widely distributed throughout the tropics, although with some variations.

Limitation of bacterial wilt in oxisols

Bacterial wilt was observed in the first crop, regardless of the amendment supplied (Table 2). However, although not immediately obtained, the positive effect of amendments was fully effective in the following crops where no wilt was observed. Disease incidence increased regularly in control plots. Urea showed only a limited effect on the disease.

Table 2. Effect of four organic amendments on the evolution of bacterial wilt in three successive susceptible tomato crops.

Treatment	% wilted crops		
	1st crop (days 12–60)	2nd crop (days 62–109)	3rd crop (days 112–155)
Control	14	24	43
Urea	22	15	26
Soybean	23	0	0
Dried sludges	41	0	0
Sterilised dried sludges	30	0	0

The delayed positive effect of amendments could be related to variations in microbial resident populations following massive nitrogen supplies. Therefore, several telluric populations were jointly monitored: (i) populations of *P. solanacearum*; (ii) those involved in the nitrogen cycle; and (iii) those potentially antagonistic to bacterial wilt.

Table 3 presents parameters of the regression curves relative to counts of telluric populations of *P. solanacearum*. The slopes of the curves obtained with the different amendments do not significantly differ from the slope of the control curve of a nonamended soil, with the exception of the soja treatment where the slope is higher. Overall, the low values of slopes (-6×10^{-3} to -1×10^{-2}) indicate that *P. solanacearum* adapts well to different forms of nitrogen supply.

Populations of bacteria, fungi and actinomycetes (Figures 6–8) did not show dramatic variation with treatments. Fungi and actinomycetes were maintained within a range limit of 2 log units up to 150 days. Populations of bacteria tended to settle around a level of 10^9 bacteria/g dry soil, although their initial variations in the first half of the recording period were larger (2.5–3 log units).

Similarly, development of microflora related to the nitrogen cycle in treated plots did not differ significantly from the untreated soil, except for the nitrifying bacteria (*Nitrosomonas*) oxidising ammonium to nitrite, in which populations were 10–100 times higher than in the control. A more detailed analysis (Fig. 9) shows that treatment is not discriminant but that it is in subsequent crops. The whole variability of analyses (57.8% and 42.2% for axes 1 and 2 respectively) is presented. It shows that flora that oxidise ammonium

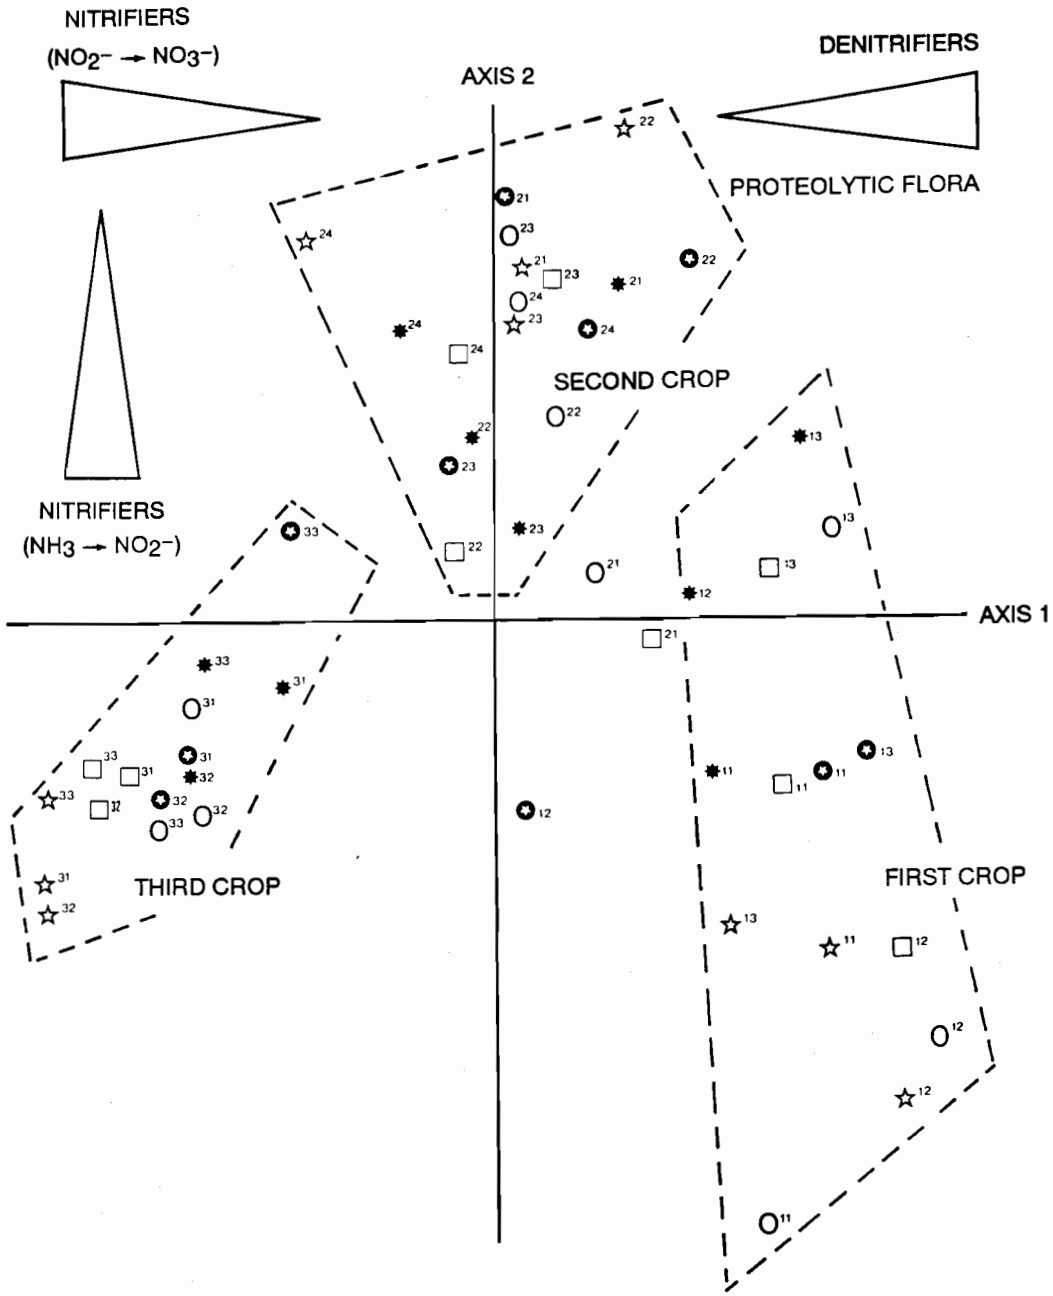

Fig. 9. Relative effects of some factors on nitrogen-related microflora represented schematically on a factorial map (after Prior and Béramis 1990). Control -✪-; Urea -✱-; Soja -☆-; Dried sludges -○-; and sterilised sludges -❑-. Each individual analysis is positioned in comparison with all others for every treatment and every crop. First figure stands for the crop rank. Second figure represents the sampling date. Arrows show trends of variables that discriminate between the three sets. These sets are separated according to the strength of the correlation of the variables (nitrogen-related microflora) with each axis. Axis 1 is correlated with flora oxidising nitrite to nitrate, denitrifiers and proteolytic flora. Axis 2 is negatively correlated with flora oxidising ammonium to nitrite.

to nitrite are favoured in the first and the second crops whereas flora oxidising nitrite to nitrate are favoured by each new crop, in contrast with denitrifiers and proteolytic microbes. It was also demonstrated that the effect of the organic amendments used here could not result from a variation of the mean soil humidity (Prior and Beramis 1990).

The absence of variation in the populations of microbes demonstrates that the observed effect does not result from a modification of inoculum of *P. solanacearum* or from a decrease of its survival ability due to either a direct nutritional effect or to microbial antagonism.

The pathogenicity of *P. solanacearum* isolates was maintained, which indicates that the reduction in wilting was limited to the period where the amendment was supplied while plant and bacterium interact under this nutrient regime. This suggests a nondurable biological effect.

Examination of the vascular bundles in plants treated with amendments showed that they were void of the bacterium, but limited necrosis of xylem tissues and malformation of the cambium in the adjacent petiole evolved slowly and resulted in an hyperplastic crack of the petiole. This suggests that high nitrogen fertiliser triggers a resistance mechanism or modifies the interaction between *P. solanacearum* and the plants.

We have not carried out experiments to support the first hypothesis (induction of a defence mechanism) and the effect of high nitrogen supplies on the physiology of solanaceous plants has not been investigated thoroughly despite some attempts in the early 1980s. Regarding the second hypothesis, modification of interactions between bacterium and plant concerns mostly the hypersensitive reaction (HR). Careful investigation of the HR in the parenchyma (Sequeira et al. 1977) drew attention to production of a bacterial elicitor that induces cell compartmentation when bacteria are recognised by the host plant. However, this recognition took place only with rough strains that have weak or no virulence. In our studies, although we have no definite information on the physiology and morphological state of bacteria in planta, cells encountered in the vessels of plants that do not wilt were assumed to be of the fluidal type. Only a few histological studies have been made on bacterial wilt despite its worldwide incidence (Wallis and Truter 1978; Schmit 1978; Petrolini et al. 1986). Whatever the organs involved, all these studies concerned wild type strains infecting young plants of susceptible tomato cultivars, grown with classical fertilization either in vitro or in controlled conditions. Therefore, further investigations are required in conditions where defence mechanisms are involved.

In Guadeloupe, amendments based on sewage sludges are favoured because of their positive effect on available nitrogen, phosphorus and subsequently yield. When used at high concentrations (*ca.* 100 t/ha), these sludges acidified soil and subsequently raised Al-exchangeable concentration (Mench and Clairon 1991). Repeated use would require monitoring of pH and previous liming to keep the properties at their optimal level.

Tropical countries have to deal, at the same time, with food requirements and care of the environment. If the restoration of an acceptable level of production through amendments cannot be applied because of the lack of readily available organic matter in numerous tropical areas, it does constitute an encouraging approach wherever local sources of organic matter are available. These local sources of organic matter should be evaluated with respect to bacterial wilt control, and environmental and profitability factors.

Conclusions and Prospects

Most reviews (Buddenhagen and Kelman 1964; Hayward 1991; Kelman 1953) have noted that there are contrasting and even contradictory reports on persistence of *P. solanacearum* in soils and assessment of the suppressiveness of a given soil. Although suppressive soils have been mentioned in various geographic areas, there is at present, no general mechanism that seems able to account for observations and experiments. Despite the lack of a comprehensive theory, soil suppressiveness has probably been exploited locally but not to a large extent, according to the available literature. Comparison of two conducive and two suppressive soils with high sand content suggested an indirect role of soil type and soil moisture that resulted in variations of microbial populations antagonistic to *P. solanacearum* (Nesmith and Jenkins 1983, 1985). This proposed mechanism is similar to that put forward in the case of soils suppressive to *Fusarium* wilt of banana (Stotzky 1972). Undoubtedly, microbial antagonism interacts with survival of *P. solanacearum* and its efficiency depends on soil conditions. The very high clay content of Guadeloupe vertisols, higher than most of those investigated previously, probably accounts for the fact that microbial antagonism is not primarily involved in the suppressiveness of these soils.

Survival ability of *P. solanacearum* was compared in soils with a significant clay content and in clay (Moffett et al. 1983). However, the range of water potential investigated corresponded to a highly hydrated state, between –3 and –150 Pa, which prevents further comparison with water potential investigated in vertisols.

In a study of 126 soil samples from Taiwan (Ho et al. 1988), approximately 25% of soils were considered suppressive. A positive correlation was established

between pH and recovery of *P. solanacearum*, whereas in our study this factor was not clearly related to suppressiveness. Unfortunately, the physicochemical characteristics of the soil samples are not available for comparison.

Breeding for resistance and cropping of resistant cultivars (Buddenhagen 1986; Messiaen 1981), despite variations in stability of resistance (Denoyes 1988; Krausz and Thurston 1975; Mew and Ho 1977), remains a major need in the tropics. This emphasises the interest in maintaining the performance of resistant plants or enhancing it through cultural practices. Improved criteria for screening plant resistance are also obviously required. The attempts to elucidate the mechanism of resistance in existing cultivars should provide a basis for this. In a recent review, Hayward (1991) stated that latent infection in potato is 'a most insidious aspect of disease biology of great concern to plant breeders'. Other recent reports on tomato (Grimault et al. these proceedings; Prior et al. 1990) indicated that latent infections are probably a general feature of plant–bacterial wilt interactions, and they propose reexamination of the current criteria used in breeding.

Because of this greater need to maintain performance of resistant plants in various adverse environments, integrated control strategies that have proven successful so far are likely to remain so in the near future.

The attempts reported here (organic amendments in oxisols, water management in vertisols) reflect the local specificities that were put together to develop an integrated control. The amendment of conducive soils allows the cultivation of susceptible or moderately resistant cultivars which was impossible before. These cultivars can be attractive to farmers for agronomic qualities or economic reasons (price, diversification, consumer demand). The management of areas with suppressive vertisols also permits growth of cultivars of higher susceptibility than previously was the case. In both situations, resistant cultivars available at present or still to come, will benefit favourable situations where risks of breakdown of resistance will be limited. It could be necessary in the future to apply the same approach to other systems of control, such as biological control.

It is likely that strategies of biological control through interspecific or intraspecific competition will in future, need local adaptations. This prospect will be a new challenge for the integrated control strategy.

Colonisation of Roots and Control of Bacterial Wilt of Tomato by Fluorescent Pseudomonads

S.T. Hsu, C.C. Chen, H.Y. Liu and K.C. Tzeng*

Abstract

Strains of fluorescent pseudomonads (FP) isolated from tomato roots varied considerably in their rhizosphere colonisation ability. The population densities of 64 strains tested in the rhizosphere of tomato at 21 days after planting of the bacteria-treated seeds ranged from nondetectable to 3.3×10^5 cfu/g wet root, with most strains in the range of 10^3–10^4 cfu/g wet root. The rhizosphere population of FP decreased gradually with plant growth and colonised only portions of root adjacent to the inoculum source. Amending soil with certain substrates enhanced colonisation of FP on tomato roots. Both rhizosphere population and colonisation frequency on root tips of tomato increased significantly by amending soil with a formulated mixture of ammonium sulfate, bone powder, castor pomace, crab meal, glycerol, siliceous slag and valine. Strains of FP also varied in their ability to control bacterial wilt of tomato caused by *Pseudomonas solanacearum* in the greenhouse test. Among 230 strains tested, only a few significantly reduced (ca 50%) wilt when used to treat roots of tomato seedlings before transplanting to the pathogen-infested soil. In vitro antibiosis of the effective FP strains against *P. solanacearum* was due mainly to their production of fluorescent siderophores. However, mutants deficient in fluorescent siderophore production from one of the FP strains (D-4) obtained by Tn5 mutagenesis did not lose their efficacy of disease control. When the soil was amended with the formulated mixture, the colonisation of strain D-4 on root systems was enhanced with an increase in the efficacy of disease suppression. Four strains of FP effective in the greenhouse test did not significantly reduce the disease under field conditions.

BACTERIAL wilt caused by *Pseudomonas solanacearum* E.F. Smith is one of the most important diseases of tomato in Taiwan. The disease is particularly destructive during summer or warm wet seasons, and has been a limiting factor in tomato production. Strains of *P. solanacearum* isolated from tomato and other host plants in Taiwan were race 1, biovar 3 or biovar 4, and all were virulent to tomato (Hsu 1991). Since commercial cultivars of tomato were susceptible to the disease, breeding for disease resistance has been the major strategy for bacterial wilt control. The Asian Vegetable Research and Development Center and other agricultural agencies have made substantial progress in breeding tomato for resistance to the disease in Taiwan (Lin and Chen 1982; Opena and Tschanz 1987). However, highly resistant cultivars have not yet been developed.

*Department of Plant Pathology, National Chung Hsing University, Taichung, Taiwan, Republic of China.

Amendment of soil with organic matter has also been studied as a means of disease control. A significant level of bacterial wilt control on tomato was achieved by amending soil with a formulated S-H mixture in greenhouse tests (Chang and Hsu 1988; Hsu and Chang 1989). The use of soil amendment to control the disease in the field has not yet reached practical application.

The objective of the research reported here was to study the possibility of control of bacterial wilt of tomato by biological means. Fluorescent pseudomonads (FP) were selected as the possible biocontrol agents, because during the last 10 years, they have been shown to be effective for controlling various soilborne pathogens and also for promoting plant growth (Suslow 1982; Weller 1988). The use of FP has been reported to be a promising measure for bacterial wilt control on several crops (Anuratha and Gnanamanickam 1990; Aspiras and Cruz 1986; Ciampi-Panno et al. 1989).

Materials and Methods

Bacterial strains

Strains of FP were isolated on King's B medium from roots of tomato plants collected from various localities in Taiwan. Strain PS95 of *P. solanacearum* isolated from an infected tomato plant was used in this study. Strains were at room temperature in screw-capped test tubes containing sterile distilled water.

Rhizosphere colonisation tests

Sixty-four strains of FP were selected for resistance to rifampicin (100 μg/mL) and nalidixic acid (250 μg/mL), and were tested for their ability to colonise the rhizosphere of tomato (cv. Known You 301) by the plastic bag assay method (Chen et al. 1992). The population dynamics of FP in the tomato rhizosphere was determined by greenhouse pot test. Bacteria-treated seeds were sown one seed per pot in pots containing a field soil, . At weekly intervals after planting, the entire root system was excised from each plant and loose soil shaken away. The root system was washed in 0.1 M solution of magnesium sulfate, and the washings plated on King's B medium containing rifampicin (100 μg/mL), nalidixic acid (250 μg/mL) and cycloheximide (50 ug/mL). Distribution of strains of FP on roots after introduction as seed treatments was determined on 14- and 28-day-old seedlings. Only the tap root with side branches removed was assayed. The tap root was cut into 2 cm sections. After washing each section in the magnesium sulfate solution, the bacterial population in the washings for each section was determined as above.

Effect of amending soil with substrates on bacterial colonisation

Nineteen organic and inorganic substrates were tested for their effect on root colonisation by FP. Tomato seeds coated with FP were planted in pots containing a field soil amended with a test substrate at a concentration of 0.5 or 0.01 %. The rhizosphere population of FP was determined 40 days after planting as described earlier. The colonisation of root tips by FP was assayed by placing 2-cm root tips on King's B medium containing the antibiotics and examining them under UV light (366 nm) 48 hours after incubation at 30°C. Six to ten root tips randomly selected from each of 6-8 plants were used for each test.

Screening strains for bacterial wilt control

Strains of FP were screened for their ability to control bacterial wilt of tomato in the greenhouse by the root-dip method. Roots of tomato (cv. Known You 301) seedlings were dipped in the suspension of FP (about 10^8 cfu/mL) for 30 minutes before transplanting to the soil infested with *P. solanacearum* PS95 (about 10^7 cfu/g dry soil). Ten seedlings were used for each treatment. The treated plants were placed in the greenhouse with temperatures ranged from 25–34°C. The disease severity was recorded 28 days after transplanting and converted to the disease index of Winstead and Kelman (1952).

Field control experiments

The experiments were conducted in the fields of the Taiwan Seed Improvement and Propagation Station, Shihshieh, Taichung. Four strains of FP that were effective in the greenhouse test were used in the field trials. In the first field test, each of the strains was used as a seed treatment. Thirty-day-old tomato (cv, Known You 301) seedlings derived from seeds treated with the FP were transplanted into field plots naturally infested with *P. solanacearum*, with two 20-plant rows per plot (7.6 × 1.5 m) and three plots per treatment. The plots were arranged in a randomised complete block design. In the second field test, each of the strains was applied as a root dip. Roots of 30-day-old seedlings treated with the FP (about 10^8 cfu/mL) for 1 hour were transplanted into field plots, with three plots per treatment. The percentage of wilted plants was recorded periodically after planting.

Results and Discussion

Rhizosphere colonisation ability of strains of FP

Colonisation of the root system by FP is thought to be an important factor in the ability of tomato plants to suppress soilborne diseases (Weller 1988). Sixty-four strains of FP initially isolated from tomato roots were therefore screened for ability to colonise the rhizosphere of tomato. The rhizosphere population varied greatly among strains of FP at 21 days after planting of seeds treated with the bacteria (Table 1). This indicates that strains of FP isolated from tomato roots differed considerably in their ability to colonise the rhizosphere. The initial bacterial inoculum level on seeds may affect the subsequent rhizosphere population density, but reports on this relationship have been variable (Bennett and Lynch 1981; Bull et al. 1991; Iswandi et al. 1987; Juhnke et al. 1989; Loper et al. 1985; Weller 1984). In the present study, the number of FP cells coated on tomato seeds among strains varied from 5.4–8.6 log cfu/seed, but the resulting rhizosphere population densities of strains from seeds coated with higher inoculum levels were not consistently greater than those of other strains from seed coated with lower inoculum levels. However, when a given strain was tested, the rhizosphere population was directly related to the initial seed inoculum levels (Chen et al. 1992).

Table 1. Colonisation capacity of 64 strains of fluorescent pseudomonads in the rhizosphere of tomato following seed treatment with the bacteria.

No. of strains	Rhizosphere population (cfu/g wet root)[a]
4	1.5×10^5–3.3×10^5
36	1.1×10^3–6.7×10^4
24	0.0

[a] Determined on 21-day-old seedlings. Five replicated plants were used for each treatment.

The population dynamics in the rhizosphere were determined for four strains that differed in colonisation ability as revealed from the result of the initial colonisation screening test. The rhizosphere population of these strains declined gradually with plant growth (Fig. 1); the populations of strains FP10 and FP3 that were better colonisers decreased more slowly than those of strains FP20 and FP34 that were less efficient colonisers. The population decline in the tomato rhizosphere observed in this study was similar to that reported for certain strains of FP tested in other plants (Kloepper et al. 1980b; Loper et al. 1985; Weller 1983). Although the population of some strains of FP applied on seeds could be detected in the rhizosphere at different stages of tomato growth, they colonised only portions of root near the point of attachment with the stem (Table 2). When the bacteria-treated tomato seeds were planted in a soil with or without autoclaving, strains of FP were detected on all portions of root in the autoclaved soil, whereas they were detected on only the portion of root near the inoculum source in the nonautoclaved soil (Chen et al. 1992). This suggests that the failure of strains of FP to migrate along the root may have been due to their inability to effectively compete with indigenous soil microorganisms. Soil microflora have been reported to have a significant effect on bacterial root colonisation (Chao et al. 1986; Davies and Whitbread 1989; Scher et al. 1984).

Effect of soil amendment on root colonisation

Since high population densities of strains of FP could not be maintained in the rhizosphere of the growing tomato plants, studies were carried out to determine if amending soil with certain substrates could increase rhizosphere colonisation. A number of substrates including ammonium sulfate, arginine, bagasse, bone powder, brewers grains, brown sugar, calcium superphosphate, castor pomace, crab meal, earcorn chops, glycerol, glycine, mannitol, marine algae, oyster shell, rice husk, siliceous slag, soybean meal and valine were tested for their effects on the rhizosphere population of a strain of FP, the root-tip colonisation by the strain and the growth of tomato plant. From the evaluation of these amendments, seven substrates were selected as candidates for formulation of a soil amendment and different concentrations of these ingredients were tested for their effect on rhizosphere colonisation. A mixture (designated CH-1) consisting of ammonium sulfate 2%, bone powder 10%, castor pomace 30%, crab meal 20%, glycerol 0.8%, siliceous slag 30% and valine 1.2% was formulated. When the mixture was applied to soil at the rate of 1%, the population of strains of FP in the rhizosphere 30 days after planting of the bacteria-treated seeds increased significantly (Table 3). Percentage of root tips colonised by a strain of FP was also increased remarkably by amending soil with the mixture (Table 4). The CH-1 mixture not only enhanced the rhizosphere colonisation by FP, but also reduced the population of *P. solanacearum* in soil (Table 5). Thus, it is possible to formulate a soil amendment which not only enhances the colonisation of FP on roots, but also suppresses the pathogen in soil.

Control efficacy of FP

The intent of the initial colonisation screening test was to select superior rhizosphere-colonising strains for use in evaluating their ability to control bacterial wilt of tomato. However, the strains tested were not considered to be efficient rhizosphere colonisers, because they were unable to migrate along roots and high population sizes were not maintained in the

growing plant. In fact, when the 64 strains used in the rhizosphere colonisation study were tested in the greenhouse, none was effective in controlling the disease. Therefore, further strains were isolated. In total, 230 strains of FP were screened by the root-dip method, but only 10 were found to reduce the disease severity significantly. In the repeat experiments, four strains, D-4, T-9-1, G-14 and 59, were more consistent in efficacy, reducing the disease index by, on average, 50–70 % (Table 6).

Production of yellow-green fluorescent pigments that function as siderophores (ferric-specific chelators that have a high affinity for iron) by FP has been shown to be involved in the control of various soilborne diseases (Leong 1986; Weller 1988). Siderophores are believed to sequester the iron in the root environment, making it unavailable to pathogens and ultimately

inhibiting their growth (Kloepper et al. 1980a). The role for the fluorescent siderophore in the control of bacterial wilt of tomato by the four strains selected in this study was therefore evaluated.

In vitro, growth of *P. solanacearum* was inhibited by strains D-4, T-9-1, G-14 and 59 on King's B medium but not on Potato Dextrose Agar (PDA). When $FeCl_3$ was added to King's B medium at 1 and 10 μM, the strains produced fluorescent pigments and also inhibited the growth of *P. solanacearum*, but when added at 100 μM or more, the strains no longer produced the pigment and also lost their inhibition activity on *P. solanacearum*. Hence, the in vitro antibiosis of the strains against *P. solanacearum* was due mainly to their production of fluorescent siderophores.

Further studies were carried out to isolate from the strains mutants deficient in fluorescent siderophore production. Five nonfluorescent mutants were obtained from strain D-4 by Tn5 site-directed mutagenesis (Simon et al. 1983). Southern hybridisation analysis of *Eco* R1-digested total DNA from these nonfluorescent mutants probed with Dig-dUTP labelled Tn5 vector, pSUP2021, revealed that they resulted from the single insertion of Tn5 into different regions of the strain D-4 genome. The nonfluorescent mutants lost their inhibitory effect against *P. solanacearum* on King's B medium, except for one mutant which showed very weak inhibitory activity. When tomato seedlings were root-treated with each of the mutants and planted in the infested soil, it was found that disease severity was reduced and did not differ significantly from that in seedlings treated with the parent strain D-4 (Table 7), indicating that loss of fluorescent siderophore production did not render strain D-4 ineffective in disease control under greenhouse conditions. The results suggest that production of the siderophore by the strain was not related to its ability to suppress bacterial wilt of tomato. The mechanism by which the strains control bacterial wilt in tomato remains unknown, but may involve mechanisms such as substrate competition and niche exclusion on the root system (Weller 1988).

Although certain strains of FP were consistently efficaceous in greenhouse tests, they failed to protect tomato from bacterial wilt in field trials (Table 8). The reasons for this are unknown, but there is no doubt that the natural field environment is much more complex than the greenhouse environment. One of the major causes of the disappointing field results may be the inability of the bacteria to multiply rapidly enough to keep pace with the continuously developing root systems of tomato throughout the season. Our prelim-

inary results revealed that although the FP strains introduced as seed or root treatments could be detected at various stages of tomato growth under field conditions, rhizosphere populations of the strains decreased with plant growth and the bacteria did not colonise the entire root system. Since, as described earlier, amendment of soil with the CH-1 mixture enhanced the rhizosphere colonisation of FP strains, the efficacy of combined treatment with the mixture and FP was tested in the greenhouse. The results showed that greater disease suppression was achieved by the root treatment with strain D-4 plus soil amendment with 0.75% CH-1 mixture than by either treatment alone (Fig. 2). The effectiveness of this combined treatment for control of bacterial wilt of tomato under field conditions is being investigated.

Exopolysaccharides of *Pseudomonas solanacearum*: Relation to Virulence

D. Trigalet-Demery*, H. Montrozier†, G. Orgambide§, V. Patry†, O. Adam†, L. Navarro†, V. Cotelle† and A. Trigalet*

Abstract

We have discovered that the exopolysaccharide fraction of *Pseudomonas solanacearum* is not a homogeneous product as previously believed, but instead is composed of four distinct polymers. We have established the structure of the major polysaccharide, which we have named X_1. This is an acidic heteropolymer, with an apparent molecular weight greater than 600kD, containing, in equimolar ratios, N-acetyl-galactosamine and two unusual amino sugars, 2-N-acetyl-2-deoxy-L-galacturonic acid and 2-N-acetyl-4-(3-hydroxybutanoyl)-2,4,6-trideoxy-D-glucose. We have also examined the X_1 fraction of several transposon-induced avirulent strains carrying mutations in the *ops*, *eps* and *hrp* gene clusters. We conclude that there is a direct correlation between the degree of virulence and the quantity of X_1 produced in vitro and in planta. In addition, preliminary information about the other polysaccharidic polymers found in supernatants of liquid cultures of *P. solanacearum* is provided.

PSEUDOMONAS solanacearum E. F. Smith, the causal agent of bacterial wilt disease, a destructive bacterial plant pathogen of economic importance. Among the bacterial compounds that could be involved in virulence, the exopolysaccharide (EPS) abundantly produced in infected xylem vessels of the susceptible host is one of the most likely candidates (Husain and Kelman 1958; Wallis and Truter 1978).

This EPS has been considered by most authors to be primarily composed of galactosamine (Dudman 1959; Whatley et al. 1980) and, more specifically, it has been pointed out that the galactosamine residues are acetylated (Akiyama et al. 1984; Drigues et al. 1985). A correlation between EPS and virulence was proposed as a result of comparisons between wild type strains that produce abundant slime (EPS) and have mucoid, fluidal appearance on agar media, and pleiotropic, spontaneous avirulent mutants which, on the same media, exhibit a rough colony morphology (Kelman 1954), and were incorrectly described as EPS$^-$. However, conflicting data have been published concerning the biochemical composition of the EPS of these various strains (Trigalet-Demery 1989), and in no case was any structure proposed.

Random mutagenesis of different virulent strains of *P. solanacearum* allowed the isolation of avirulent mutants. An approach to demonstrate the correlation between EPS and virulence has recently been attempted by using these insertion-induced avirulent mutants, which are impaired in both virulence and production of N-acetyl-galactosamine (Denny et al. 1988; Xu et al. 1988). These studies again led to conflicting results, also probably because of a lack of precise chemical definition of the EPS.

We have demonstrated the high degree of heterogeneity of the EPS of *P. solanacearum* wild type GMI1000 and have established the structure of the major acidic heteropolymer, which we have named X_1 (Orgambide et al. 1991). Several clusters of genes involved in the biosynthesis of EPS have been identified and recent genetic evidence suggests that EPS is in fact a virulence factor of *P. solanacearum*. These EPS biosynthesis gene clusters include the *eps*I

and *eps*II gene clusters (Denny and Baek 1991) [*eps* = exopolysaccharide] and the *ops* gene cluster (Cook and Sequeira 1991) [*ops* = outer polysaccharides].

Mutants that are affected in both pathogenicity and the development of a hypersensitive response have been available for some time (Boucher et al. 1985). The mutations have been mapped to an *hrp* gene cluster (Boucher et al. 1987) [*hrp* = hypersensitive response and pathogenicity]. Recent advances concerning the transcriptional organisation (Arlat et al. 1992) and potential function(s) of this gene cluster (Genin et al. 1992) have been presented. The majority of these *hrp* mutants grown on agar media have a colony morphology which is comparable to that of the parental wild type.

Here we report the results of comparative biochemical studies on transposon-induced avirulent mutants located within the *ops*, *eps* and *hrp* gene clusters. Our aim was to relate production of X_1 to virulence. Preliminary results on the biochemical characterisation of the three other polysaccharidic fractions (X_2, X_3, and X_4) isolated from the supernatant of liquid bacterial cultures are also presented.

Experimental Procedures

The bacterial strains used in this study are listed below. Their origin and relevant characteristics are described in the papers cited: GMI1000 (wild type) and its derivatives mutated within the *hrp* gene cluster—GMI1332, GMI1333, GMI1352, GMI1353, GMI1355 (Boucher et al. 1987, 1988); GMI1425, GMI1446, GMI1492, GMI1500, GMI1501 (Arlat et al. 1992); Delta 47 and Delta 199 (Boucher, unpublished data), GMI8172 (Frey et al. 1992); -K60 (wild type) and its derivatives mutated within the *ops* gene cluster—KD500-197, KD500-45, KD500-71, KD500-127, KD500-41 and KD500-13 (Cook and Sequeira 1991); and KD700 and KD710 which are mutated in the *eps* gene cluster (Cheng et al., 1992).

Experimental procedures have already been described (Orgambide et al. 1991), but are briefly summarised. The bacteria were grown in liquid media for 30 hours at 30°C on a rotary shaker in rich BG medium and in minimal MM medium supplemented with glucose (Boucher et al. 1987). The liquid culture was centrifuged and the supernatant precipitated overnight at 4°C with six volumes of cold ethanol. The precipitates were dialysed over a XM50 membrane (Amicon, Co.) and lyophilised. The crude extracts were purified by successive washing with chloroform and chromatographed over a cation exchange AG 50WX12 (H^+) resin and lyophilised; this is referred to as total, purified EPS.

EPSs were also isolated from root-infected tomato plants. As soon as the first symptoms of wilting appeared, surface-sterilised stem pieces were soaked for 20 minutes in sterile water and EPS was purified from the soaking liquid by ethanol precipitation.

The heterogeneity of the material was revealed by gel filtration of the total EPS over Sephacryl S-500 (Pharmacia) under dissociative conditions and by anion exchange DEAE-Trisacryl M (IBF, Biotechnics) chromatography under dissociative conditions with a NaCl gradient as eluent. All fractions were methanolysed with anhydrous methanolic chloride and analysed by gas–liquid chromatography. All ^{1}H-and ^{13}C-NMR spectra were recorded on a Brucker AM 300 WB instrument equipped with an Aspect 3000 calculator.

Results and Discussion

As a result of our biochemical analysis of the EPS of *P. solanacearum* we can summarise our present knowledge as follows. Four polysaccharidic fractions, which we have named X_1, X_2, X_3, X_4, can be isolated from the bacterial supernatants. X_1, the major acidic fraction (Orgambide et al. 1991) was composed of the repetition of a trisaccharidic unit involving N-acetyl-galactosamine and two unusual amino-sugars, the 2-acetamido-2-deoxy-L-galacturonic acid and the 2-acetamido-2,4,6-trideoxy-4-(3-hydroxybutyramido)-D-glucose, in equimolar ratio: →3)D-GalNA*cp* (α1→3) 4-OAc-LGalNacA*p*(α1→3)DBac2NAc4-N[3OHBut]*p* (β1→; X_2, mannan-rich poly-mers; X_3, a rhamnose-rich polymer; and X_4, a family of glucans.

X_1, the major, acidic polysaccharidic fraction, is produced in rich and minimal liquid media by the virulent strains GMI1000 and K60, as well as by all of the avirulent *hrp* mutants so far tested. The quantity of X_1 produced by all these *hrp* mutants in liquid media is comparable to that of the parental virulent strain GMI1000, with the exception of the deletion Delta 199 (18 kb out of a total of 23 kb of the whole *hrp* gene cluster) which produces half as much as the wild type. The structure of X_1 is always strictly identical to that already established (Orgambide et al. 1991) whatever the strain or medium so far examined. Since these mutations (transposon insertions and large deletions) together cover most of the *hrp* gene cluster and do not apparently affect the structure or reduce significantly the amount of X_1 produced, we conclude that this gene cluster is not involved in the biosynthesis of X_1.

K60 and most of its transposon-induced derivatives produce the X_1 polymer in rich liquid medium, although there are differences in the levels (Table 1). There is a direct correlation between the amount of X_1 produced by the mutants KD500-71, KD500-45, KD500-41, KD500-13 and KD500-127 and their aggressiveness; the more X_1, the more pronounced are wilting symptoms. In addition, mutants KD500-197

and KD700, which do not produce any X_1, are strictly avirulent. Mutant KD710 however, which produces no X_1, does induce some wilting in rich medium. The locations of the mutants KD700 and KD710 are not precisely known, but they are located on either side of the *espI* gene cluster as defined in the paper by Denny and Beak (1991). It may be possible that the production of EPS by mutant KD710 is plant-inducible and that this mutant is located in the *epsII* region (Denny and Beak 1991).

Table 1. Relation of virulence to the amount of X_1 produced in rich liquid medium.

Strain designation	Virulence[a]	Relative content of X_1[b]
K60 (*wild type*)	100	100
KD500-127 (*opsC*)	90	61
KD500-13 (*opsB*)	80	58
KD500-41 (*opsD*)	45	27
KD500-45 (*opsB*)	29	16
KD500-71 (*opsC*)	4	Traces
KD500-197 (*opsA*)	0	n.d[c]
KD700 (*eps I*)	0	n.d
KD710 (*eps II*?)	35	n.d

[a]Virulence was estimated as the percentage of tomato plants wilted, 3 weeks after root inoculation (Trigalet and Demery 1986).
[b]Relative content of X_1 is expressed as dry weight of the polymer obtained from the same aliquot of total purified EPS from virulent and related avirulent mutants.
[c]n.d. = not detected

The X_1 polymer is produced in planta by strain GMI1000; for example, 100 inoculated plants yielded about 60 mg of total EPS. In preliminary experiments with strains KD700 (*epsI*) and GMI1353 (*hrp*) EPS production in planta was not detected under similar inoculation and incubation conditions, probably because KD700 does not invade the susceptible tomato plants used and because the invasiveness of strain GMI1353 is rather poor compared with that of the wild type strain GMI1000 (Trigalet and Trigalet-Demery 1990).

The mannan polymer(s), the X_2 fraction, is readily isolated from total EPS, obtained from rich medium, by chromatography over DEAE-Trisacryl. A polymer that accounts for about 10% of the total EPS after a 30 hour culture period, has been identified as a $\alpha 1 \rightarrow 2$, $\alpha 1 \rightarrow 3$, and $\alpha 1 \rightarrow 6$ linked mannose residue polymer, which is attributed to a previously identified mannan produced by yeast (Montrozier, unpublished data). This mannan can be readily isolated from the bacto yeast extract (Difco) used in rich medium and is therefore a contaminating polymer. However, small amounts of mannose have been identified by gas–liquid chromatography in the total EPSs from GMI1000 and related *hrp* mutants when cultivated in minimal liquid medium, i.e in the absence of bacto yeast extract. At the present time, however, it is difficult to decide whether *P. solanacearum* does produce a mannan in minimum medium, since the putative polymer is present in minute amounts and is not yet structurally characterised.

The rhamnan polymer, X_3, is a minor fraction that accounts for less than 5% by weight of total EPS. The X_3 fraction is isolated by gel permeation as a polymer whose apparent molecular weight is between 5000 and 15000 (there may be some association of small repeating units). Rhamnose is a labile sugar, sensitive to usual hydrolysis conditions, and supposing that rhamnose is part of X_1, as a lateral branch for instance, it could readily be separated from the major polymer under our hydrolysis conditions. However, the latter remarks are inconsistent with the data obtained from the biochemical analysis of mutant KD500-45, which is X_1^i and X_3* (i = impaired, and * = identical to wild type) and mutant KD500-13, which is X_1* and X_3^- (– = not detected).

It should be noted that rhamnose is a principal sugar component of the lipopolysaccharide (LPS) of *P. solanacearum*, and that it accounts for about 45% of total carbohydrate of the LPS of GMI1000 and is located in the outer core and in the O-antigen (Drigues et al. 1985). Liquid culture media may probably contain some degraded LPS as the result of bacteriolysis and one can predict that incomplete O-antigen is present in the supernatant. In fact, recent data (Montrozier, unpublished data) indicate that a tetrasaccharidic unit composed of three rhamnose and one glucosamine can be isolated from the total, purified EPS of GMI1000. Similar tetrasaccharides have already been reported from other *P. solanacearum* strains (Akiyama et al. 1984; Kocharova et al. 1992).

A family of glucans, fraction X_4, has been isolated by cation exchange and permeation gel chromatography over a range of Biogel media. These glucans are produced in rich and minimal media and their structure is under study. Some avirulent mutants, namely KD500-71, KD700 and KD710, appear helpful in this respect as their EPS is essentially made of glucans.

Work is in progress to determine the structure of the different polymers under study and to establish their potential role(s) in virulence.

Lysogeny and Lysotypes of Malaysian Strains of *Pseudomonas solanacearum*

Hiryati Abdullah*

Abstract

Thirty-two isolates of *Pseudomonas solanacearum* were screened for phages. Forty-three percent of the isolates tested were lysogenic. Only one isolate was lysogenic without induction, while the others were lysogenic upon induction with various concentrations of mitomycin C. The reactions of 68 *P. solanacearum* isolates to the phages showed that no bacterial isolate was lysed by all the phages and none of the isolates was completely resistant to all the phages. Based on the lytic response of five selected phages, 13 lysotypes were distinguished. All isolates could be typed. Phages may also be useful in studies related to epidemiology and genetics.

PSEUDOMONAS solanacearum is subject to infection by bacteriophages (phages). The interaction of phages with phytopathogenic bacteria, including their potential for disease control, has been the subject of several review articles (Civerolo 1972; Okabe and Goto 1963; Videvar 1976). Phages have been used in epidemiological studies (Baldwin and Goodman 1963; Kauffman and Reddy 1975; Tagami 1959; Wakimoto 1954; Wakimoto 1960;); in classification and identification (Billing 1963, 1970; Stolp and Starr 1964; Wakimoto, 1960); in distinguishing fine differences in host specificity and differences between distinct pathogens on a single host (Freigoun and Crosse 1975; Garret et al. 1966; Persley and Crosse 1978); and in genetical studies (Boucher et al. 1977; Faelen and Toussaint 1976).

Typing phages against a bacterial species enables grouping of lysosytes within the species, based on sensitivity to the phages tested. Okabe and Goto (1963) indicated that some lysotypes are specialised in their pathogenicity or biochemical characters or both, while others are not specific. Lysotypes specific for pathogenicity or other characters are useful for identifying specialised types in nature, while the nonspecific lysotypes are a useful label for studying various aspects of the pathogen such as the mode of dispersal, infection source and longevity in nature.

*Department of Plant Protection, Faculty of Agriculture, Universiti Pertanian Malaysia, 43400 UPM, Serdang, Selangor Darul Ehsan, Malaysia.

Paulin and Nassan (1978) carried out phage-typing of 61 strains of *E. chrysanthemi* from four different hosts and isolated 32 temperate phages. They showed a degree of correlation between phage sensitivity and geographic origin of the strains. Using 12 virulent and temperate phages, Okabe and Goto (1953) divided strains of *P. solanacearum* into 40 lysotypes.

This study sought to isolate temperate bacteriophages of *P. solanacearum* and to evaluate their use in typing strains of the pathogen.

Materials and Methods

Isolation of temperate phage

Thirty-two isolates of *P. solanacearum* were screened for temperate phages. Twenty millilitre aliquots of Casamino-asid peptone glucose (CPG) broth (Cuppels et al. 1978) were inoculated with 0.5 mL of a suspension of a 24–48 hour culture of *P. solanacearum* in sterile distilled water with a concentration of 8×10^8 cfu/mL. Flasks were incubated for 16 hours at 30°C in an incubator-shaker set at 100 rpm. Initially no induction was done, but in the second and subsequent experiments isolates that did not have phages were subjected to 1, 1.5, 2 or 4 μg/mL of mitomycin C (Sigma Chemical Co., St. Louis, MI). Mitomycin C was dissolved in distilled water and added to the broth culture to give the required concentration. The culture was incubated for another 4 hours in the dark under the same conditions as previously. The contents of the

flask were then transferred to a sterile screw-capped test tube and chloroform added to a final concentration of 5%. Using a vortex mixer, the contents of the tube were shaken vigorously for 60 seconds. Tubes were incubated for a minimum of 4 hours at 20°C and stored at 4°C. Twenty microlitres of the broth were spotted on lawns of potential indicator strains. The indicator lawn (0.5 mL of the indicator strain in aqueous suspension containing approximately 10^8 cfu/mL) was streaked onto a thin layer of buffered soft water agar overlayer (3 mL), which had been poured over yeast extract glucose agar (YA) medium. Plates were incubated at 30°C for 16–24 hours. Those that produced a clear area at the inoculation points were serially diluted in buffered saline solution. Twenty microlitre aliquots of a series of its ten-fold dilution were spotted on indicator lawns. Plaques were purified through three successive single isolations of plaques and stocks prepared. Filter-sterilised stocks were then kept under 1% chloroform at 4°C.

Typing of bacteriophages

Determination of the routine test dilution (RTD) of all the typing phages was carried out using standard procedure described by Adams (1959). Stock suspensions of each phage isolated were diluted to the RTD before each typing. The reactions of 68 isolates of *P. solanacearum* to bacteriophages were determined by the standard technique. A 0.5 mL aliquot of an aqueous suspension (1×10^8 cfu/mL) of the *P. solanacearum* isolate to be tested was added to 3 mL of molten buffered soft water agar maintained at 48°C. The two components were mixed and poured over YA plates to form a complete lawn of the test bacterium on the surface. Plates were allowed to dry and 15 µL aliquots of the typing phages, which were diluted to their RTD and 10×RTD levels, were spotted on the bacterial lawn. Plates were incubated at 30°C for 24 hours.

Results and Discussion

Presence of plaques on the spotted area as a result of dilution indicates the presence of phages, while broth containing bacteriocins produced increasingly hazy inhibition zones with increased dilution, as indicated by Billing (1969). Temperate phages were readily isolated from lysogenic strains of *P. solanacearum*. Of the 35 isolates tested for lysogeny, 15 (43%) were lysogenic (Table 1). However, only one isolate (20019)

from ginger, produced phage without induction. The rest of the lysogenic strains produced phages following induction with various concentrations of mitomycin C. Fourteen phages were isolates and given tentative designations (Table 2). A phage is considered different when it originated from a different host or when it produced different plaques (of different opacity and/or diameter).

All phages produced plaques which were 1 mm or less in diameter. They were of variable opacity, but all had irregular borders. Plaque development of all phages on *P. solanacearum* isolates tested was slow, so that only a few plaques were visible by 16–24 hours, although lawn development was excellent. However, by 40–48 hours, plaques were seen more readily. The results of the reactions of phages to *P. solanacearum* isolates were more consistent when using phage stocks diluted to RTD × 10 rather than RTD. Among the *P. solanacearum* isolates, variable results were obtained. No bacterial isolate was lysed by all the phages and none of the isolates was completely resistant to the phages tested. By eliminating some of the phages with similar host ranges and those which could lyse only few strains, a simplified typing scheme using five phages was obtained. Thirteen lysotypes could be distinguished among the *P. solanacearum* isolates (Table 3). All isolates could be typed. These could not be correlated to host-plant origin or locality of isolates. However, phages could be useful in both epidemiological and genetical studies. Okabe and Goto (1961) described 13 pathotypes in Japan. They also indicated that there was not always a correlation between biochemical properties and phage sensitivity when compared with host range and virulence for different hosts.

A Biocontrol Agent for *Pseudomonas solanacearum*

G.C. Wall and J.L. Sanchez*

Abstract

Bacterial wilt is a serious disease of solanaceous crops throughout Guam. Fields often become chronically infested with its causal agent, making it unprofitable for farmers to produce these crops. At present, resistant cultivars are either inadequate or unavailable, and grafting methods are labour-intensive. For these reasons, an attempt was made to find a bacteriophage capable of attacking the local strain of *Pseudomonas solanacearum*. Soil samples were obtained from fields with a history of bacterial wilt, and from adjacent fields free of the problem. Bacteriophage activity against the local strain of *P. solanacearum* was found in both soil types, but higher counts were found in uninfested soils.

BACTERIAL wilt is a serious plant disease problem affecting many valuable solanaceous crops, including tomatoes, bell peppers, eggplant, tobacco and potatoes (Persley 1986). The first three of these crops are extremely important cash crops in tropical regions such as Guam. The disease is caused by a soilborne bacterium, *Pseudomonas solanacearum*. Infection takes place through wounds or cracks in the roots, rendering the vascular tissue incapable of transporting water and nutrients to the aerial parts, which eventually wilt and die.

Once established in a field, the pathogen is very difficult to control. There are no chemical means of control. Resistant cultivars only exist in only certain of the plant species affected. Breeding efforts in the past have failed to solve the problem, and cultural methods such as grafting to resistant rootstock and rotating fields to sugarcane or rice are labour-intensive or otherwise inappropriate.

Many bacteria, plant pathogenic and otherwise, have very specific natural enemies known as bacteriophages, or phages. Bacteriophages are submicroscopic viruses capable of penetrating their host cells and multiplying within them, using the cells' components and biochemical pathways to their own advantage. Indeed, phages are so specific that they can be used to identify their bacterial hosts in certain cases (Cuppels 1984). For obvious reasons, host specificity is an ideal attribute for biocontrol agents.

*CALS/AES, University of Guam, Mangilao, GU 96923, Guam.

The study reported here sought bacteriophages capable of attacking the bacterial wilt pathogen, for possible use as biocontrol agents.

Materials and Methods

Farmers' fields with a history of bacterial wilt problems were identified through the Cooperative Extension Service. Other fields apparently free from the pathogen were also chosen. Soil samples were collected from the top 20 cm of soil. These were taken at several points in a particular field and later combined to form a composite 150 g sample. Samples were collected as follows: 1. potted soil originally taken from the Santos farm, Mangilao; 2. Watson farm, Radio Barrigada; 3. the same farm as 2, different field; 4. Taitano farm, Yigo; and 5. Department of Agriculture, Mangilao. All samples except 1 and 2 had previous wilt history.

Isolates of *P. solanacearum* were obtained from wilted tomato plants collected from the Taitano farm in Yigo. Isolates were grown on King's Medium B. Gram-negative isolates not producing fluorescent pigments were selected (Schaad 1988). These were further screened by inoculating tomato seedlings. Only two isolates capable of reproducing wilt symptoms on the seedlings were used for the rest of this procedure.

A method first described by Crosse and Hingorani in 1958 (Johnson and Curl 1972) and used for isolating bacteriophage from *P. morsprunorum* was followed with slight modifications. Each composite soil sample was first enriched by placing it in an Erlenmeyer flask and adding 150 mL of a 48-hour culture of

P. solanacearum in nutrient broth plus 2% glycerine. Cultures were grown in a waterbath-shaker at 32°C. The free liquid was then decanted from the enrichment and passed through filter paper. This filtrate was then passed through a 0.4 μm filter (Millipore) to eliminate larger diameter particles including bacteria.

A serial dilution was prepared by taking 1 mL of the final filtrate and mixing it with 9 mL of a 24-hour nutrient broth culture of *P. solanacearum*. After thorough mixing, 1 mL of this suspension was transferred to another 9 mL of *P. solanacearum* culture, and repeated until a 10^6 dilution was prepared. All dilutions were replicated twice. Aliquots of 1 mL of each dilution were then transferred to test tubes containing 9 mL of melted agar medium at 42°C. The agar medium consisted of 1% agar, 0.5% peptone, 0.3% yeast extract, and 2% glycerine. The pH was adjusted to 7.2 with phosphate buffer. The agar mixture was shaken and poured into sterile culture dishes. Plaques were observed over a period of 48 hours.

Results

Cleared zones in a radial pattern amid the more opaque bacterial growth revealed bacteriophage activity. Selecting the appropriate range for an accurate count of plaques per plate was possible because of the serial dilutions prepared. The highest numbers of bacteriophages were found in soil samples from the potted soil originally collected from the Santos farm in Mangilao, and a sample from the Watson farm in Radio Barrigada (Table 1; samples 1 and 2). Numbers of bacteriophages per gram of soil sample were 1×10^8 and 2.4×10^7 respectively.

Discussion

High bacteriophage counts were found in soils with no bacterial wilt problem. The lower counts came from samples taken from infested fields. Our data strongly suggest that bacteriophages play an important role in the population dynamics of *P. solanacearum* in the soil, and that their use as a biocontrol agent may hold promise. The fact that these are locally occurring phages has at least two immediate advantages. One relates to quarantine: since no importations are required no permits would be needed to begin research. The other relates to specificity: these are bacteriophages that attack the local strain of *P. solanacearum*.

It is interesting that sample 1 originally came from an infested field, but has been kept in pots for over 3 years. While the soil has been used to produce diseased plants it seems to be no longer infested, as susceptible pepper seedlings fail to wilt when transplanted to it.

It is also interesting to note that part of the technique used in isolating phages includes the enrichment of these by the addition of host culture to the soil samples. Future research might perhaps answer the question of whether increasing the host population in field soil would eventually lead to phage population levels capable of controlling the wilt problem, as appears to have occurred in the potted soil of sample 1.

Phages can have negative as well as positive impacts. For example, commercial bacterial fermentation processes for the production of various drugs, foods, drinks, and pesticides are occasionally plagued with phage epidemics (C. Gonzalez, pers. comm.). Commercial companies have had to research this problem and one of the solutions employed is to isolate plaques and bacteria from areas that failed to plaque. Eventually, resistant strains of bacteria are thus developed, and the phage epidemics are controlled with these resistant strains. Returning to the context of soilborne diseases, this suggests that field populations of *P. solanacearum* might eventually undergo a natural selection process and evolve as a resistant strain if bacteriophages apply severe selective pressure. While biocontrol of *P. solanacearum* with bacteriophage may thus be possible, the success may in turn be limited by natural selection. More research is needed to clarify these issues.

Table 1. Counts of bacteriophages (phage nos/g soil) in Guam soil samples from bacterial wilt-free and wilt-prone fields.

Sample no.	Phage count	Wilt prone
1	1×10^8	No
2	2.4×10^7	No
3	10	Yes
4	400	Yes
5	20	Yes

Potential of Biological and Chemical Control of Bacterial Wilt

G. L. Hartman*, W.F. Hong*, Hanudin† and A.C. Hayward§

Abstract

Strains of biological control agents *Pseudomonas cepacia*, *P. fluorescens*, and *P. gladioli* inhibited growth of *P. solanacearum* on culture medium. A *P. cepacia* cell suspension applied to soil 7 days before inoculation with *P. solanacearum* reduced the occurrence of wilt by 65% compared with the control. A combination of *P. fluorescens* and an experimental bactericide (Terlai) was tested for control of bacterial wilt in pot culture studies. Terlai effectively controlled bacterial wilt, especially when applied before and after inoculations with *P. solanacearum*. Plants grown in green-manure-amended soil in pot culture had significantly less wilt than occurred in nonamended soil. Survival of *P. solanacearum* in soil under controlled conditions was reduced when soil was amended with KNO_3, $NaNO_3$, NaCl, and KCl at a rate of 1:99 salt to soil, but not when amended with liquid pig effluent at 1, 5 and 10%. $NaNO_3$ reduced the population to 65% that of the control.

BACTERIAL wilt caused by *Pseudomonas solanacearum* is one of the major constraints to production of solanaceous crops, especially tomatoes. The disease has been reported to cause 29% loss of fresh fruit production in hybrid tomatoes in Taiwan (Hartman et al. 1991), and its importance and occurrence has been well documented (Hayward 1991; Kelman 1953).

Research on microbial antagonists, such as *P. fluorescens* has shown some promise in control of bacterial wilt (Hsu et al., these proceedings). In addition, various Actinomycetes, and bacteria including *Bacillus mesentericus, B. megaterium, B. subtilis, B. mycoides,* and *Erwinia,* have been reported to be active biological control agents (Kelman 1953). Aspiras and Cruz (1986) treated infested soil with *B. polymyxa* and *P. fluorescens*, which increased the survival of tomato from 0% without the antagonist to 60 and 90%, respectively. *P. cepacia*, another potential biological control agent, was shown to occur in high numbers in association with maize grown as a rotation crop with potatoes to reduce the incidence of wilt (Elphinstone and Aley, these proceedings). It also has been shown to produce ketoglutonic acid which is also inhibitory to *P. solanacearum* (Akiyama et al. 1984).

Organic amendments have been used with some success in controlling bacterial wilt. Reports of using a mixture called SH (Sun and Huang 1985) or its components have been tested in Taiwan (Chang and Hsu 1988; Hsu and Chang 1989; Hartman and Yang 1990). The SH amendment is now commercially available in Taiwan.

There are no bactericides available for chemical control of bacterial wilt, though an experimental formulation, Terlai, has been tested recently in Taiwan under both greenhouse and field conditions. Growers may find that chemical control is not cost-effective.

Additional management practices to control bacterial wilt are crop rotation, intercropping or incorporating green manure crops such as Sun hemp and mungbean before planting a susceptible crop. There is some evidence that maize may reduce the occurrence of bacterial wilt either intercropped (Autrique and Potts 1987) or in the next crop (Elphinstone and Aley, these proceedings).

The purpose of our studies was to evaluate whether certain biological, organic, and inorganic treatments are effective in reducing population levels of *P. solanacearum* and thus the severity of bacterial wilt.

Material and Methods

Tests for antagonism

P. solanacearum strain PSS 4 was streaked from a stock culture stored in distilled water onto a tetrazolium chloride medium (Kelman 1954), and incubated for 48 hours at 30°C. A single, fluidal, wild-type colony was selected and increased on 523 medium at 30°C for 24 hours before harvesting cells. Suspensions were adjusted to 10^8cfu/mL or an optical density of 0.30 (equivalent to 50% transmittance) at wavelength 600 nm for all experiments.

P. fluorescens strain PF 59 obtained from S.T. Hsu, National Chung Hsing University Taiwan, ROC, was streaked on King's B medium and incubated at 30°C for 24 hours, then placed under ultraviolet (UV) lamp to detect the presence of fluorescent colonies. *P. cepacia* (Pc5) and *P. gladioli* (Pg10) were isolated from modified SM-1 (Chang and Hsu 1988) by dilution plating of AVRDC soils. Both organisms were identified using Biolog Microstation™ system 3.00. The antagonists were multiplied on 523 medium at 30°C for 24 hours.

Antagonists were streaked down the middle of dishes containing King's B medium, incubated for 48 hours and challenged by cross -streaking four strains of *P. solanacearum*. This experiment and variations of it were repeated several times.

Thirty day old L390 plants were treated as follows: 1. Pg10 applied to soil 7 days before inoculating *P. solanacearum*; 2. Pg10 applied 1 day before inoculation; 3. Pg10 applied 1 day after inoculation; and 4. only *P. solanacearum* inoculated. To apply the antagonist, 4 L of a suspension of Pg10 at a concentration of 10^9 cfu/mL (OD = 0.50) were poured in trays (35 × 50 × 7 cm) containing 16 potted plants which were soaked in this suspension for 3 hours.

Application of *P. fluorescens* and Terlai

P. fluorescens was applied as previously described for Pg10. Ten grams of Terlai, a systemic bactericide [Ching Mow Trading Co, Ltd., Taiwan, similar to 2,2-dichloro-N(2hydroxy-1(hydroxy-methyl)-2-(4-nitrophenyl) ethyl) acetamide], were added to 1 litre of tap water, then 30 mL of this suspension were poured into each pot containing one tomato plant. Treatment combinations are presented in Table 1.

Seeds of tomato line L 390 were sown directly in 8.5-cm-diameter plastic pots containing sterile soil. These were placed in a pipe-house at 30°C. Plants were inoculated 30 days after sowing (DAS) with PSS 4 by drenching soil with 30 mL/plastic pot. Each treatment contained four pots arranged in a randomized complete block design. The inoculated plants were placed in a greenhouse at 32°C. The experiment was repeated. Numbers of wilted plants were counted every 3 days beginning from 6–21 DAS. Area under the disease progress curves was calculated (Shaner and Finney 1977).

Table 1. Treatment combinations using Terlai (Tr) and *P. fluorescens* (Pf) to control bacterial wilt in greenhouse-inoculated tomatoes.

Treatment code[a]	Days after sowing

Population dynamics and plant survival in amended soil

Soil collected from an AVRDC field was air-dried and sieved through a 50 µm mesh screen. The soil was divided into eight parts containing 500 g each and amended with either liquid pig effluent at concentrations of 1, 5 or 10% (v/w), or with KNO_3, $NaNO_3$, NaCl or KCl, each at a 1% w/w. Amended or non-amended soil was mixed evenly with a 75 mL suspension of *P. solanacearum* at a concentration of 10^8 cfu/mL. Soil samples stored in plastic bags were placed in an incubator at 28°C for 5 weeks At 0, 4, 11, 18, 25 and 32 days after inoculation (DAI), 10 g of soil were removed, shaken in 90 mL of sterile distilled water and tenfold series dilutions were made. From each dilution, 0.1 mL was spread onto the plates of modified SM-1. Two plates were used for each dilution. Colonies of *P. solanacearum* were counted 48 hours after incubation at 30°C. A completely randomised design with three replications was used in this trial. Population counts were transformed to $\log_{10}$ before analysis.

Green manure

Roots and stems of sun hemp (*Crotalaria* sp.) of 70-day-old field-grown plants were chopped into pieces

before mixing 30 g fresh weight with 500 g infested soil in plastic bags. Infested soil was prepared by adding 75 mL of bacterial suspension with 10^8 cfu/mL to meshed air dry soil to field capacity. Whole plants of mungbean and soybean were also tested. There were five replication for each amendment. All the samples were incubated at 32°C and populations were monitored weekly as previously described.

Soil containing 0, 2, 6 and10% chopped sun hemp was incubated for 4 weeks before adding a bacterial suspension (OD = 0.3 at 600 nm) into the amended soil at the ratio of 1:10 (v/w). After mixing the soil, it was distributed in clays pots (30 cm diameter), using 10 pots for each level of amendment. Four-week-old L390 plants were transplanted into the incorporated soils, one plant per pot. Wilt was recorded weekly for 8 weeks.

Results and Discussion

Tests for antagonism

Modified SM1 medium allowed for the isolation of both *P. cepacia* and *P. gladioli* and it seemed not to restrict growth or number of colonies of Pg10 on SM1 compared with King's B medium (Fig. 1). *P. cepacia*, *P. fluorescens* and *P. gladioli* caused large zones of inhibition of *P. solanacearum* (Fig. 2, Pc5 not shown). Bacterial wilt was controlled when *P. gladioli* was applied to the soil before inoculation of *P. solanacearum*. Although control was not complete, there was about 60% reduction in wilt compared with the control when isolate Pg10 was applied to the soil 7 days before inoculating *P. solanacearum*.

Biological control agents are often effective in reducing pathogen growth in cultural studies and sometimes also in pot culture studies. However, there has been little evidence that these biological control agents are effective against bacterial wilt in the field. More work is needed to develop better delivery techniques, and to understand more about the soil ecology so that antagonistic activity can be enhanced.

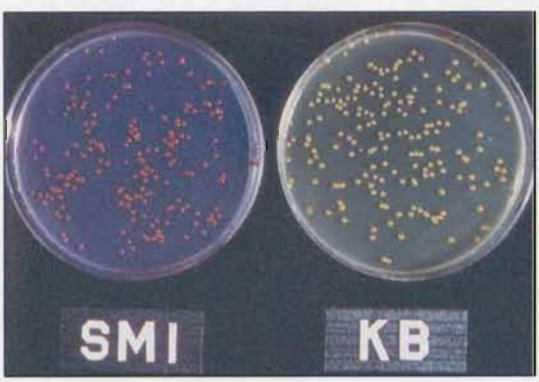

Fig. 1. *Pseudomonas gladioli* on selective medium (SM1) and on King's B medium after 48 hours of incubation.

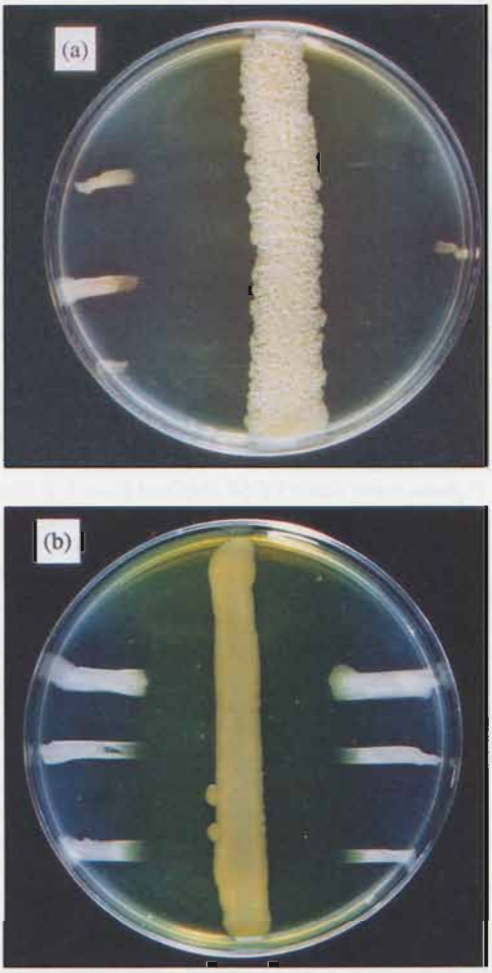

Fig. 2. Inhibition of *Pseudomonas solanacearum* by (a) *P. gladioli* and (b) *P. fluorescens* on King's B medium.

Application of *P. fluorescens* and Terlai

Terlai and *P. fluorescens* applied together were effective in controlling wilt compared with the control (Fig. 3). Terlai applied before *P. solanacearum* inoculation followed by an application of *P. fluorescens* and then a second application of terlai was more effective and consistent in reducing wilt.

Although Terlai is not available commercially, it may reach farmer use if it works in the field and is cost-effective. We did not study the effect of Terlai on other organisms, and so do not know if it may reduce potential soil antagonists.

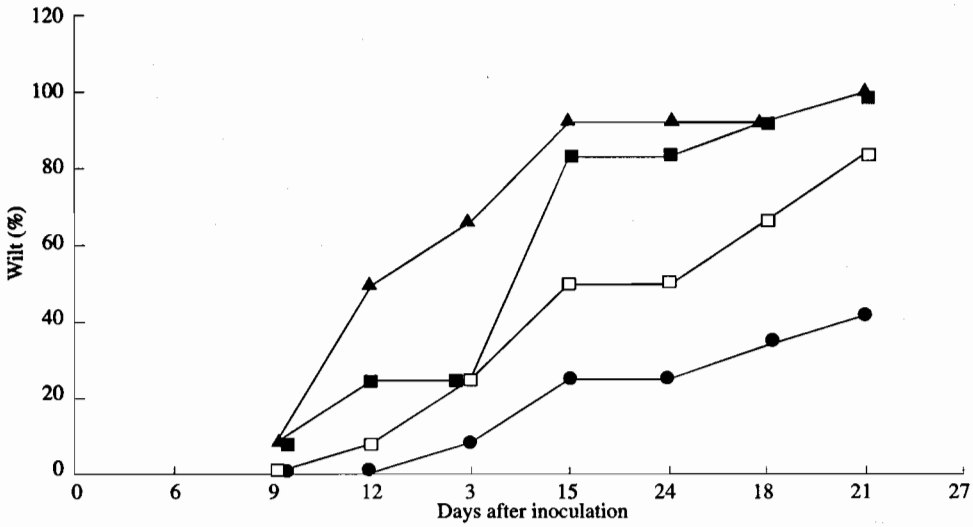

Fig. 3. Disease progress curves of bacterial wilt of tomatoes inoculated with *Pseudomonas solanacearum* (control), or protected with Terlai (Ter) and/or *P. fluorescens* before inoculation with *P. solanacearum*. Control - ▲-; Pf-Ps -■-; Ter-Ps -□-; Ter-Pf-Ps-Ter - ●-.

Population dynamics and plant survival in amended soil

Survival of *P. solanacearum* in soil was reduced when soil was amended with KNO_3, $NaNO_3$, NaCl or KCl at a concentration of 1% w/w (Table 2). Soil amended with pig effluent at 1, 5 or 10% (v/w) was not effective in suppressing *P. solanacearum*. Soil incorporated with salts significantly ($P=0.05$) reduced the population at 11 DAI. Among the inorganic salt treatments, $NaNO_3$ reduced the population to a non-detectable level 25 DAI. Sodium nitrate suppressed the population to 65% of the control. The salt group was more effective compared with pig effluent or the control in reducing population levels (Fig. 4). The salts reduced populations at 4 DAI, whereas pig effluent was not effective and was not significantly different from the control.

Green manure

Sun hemp reduced the bacterial population after 4 weeks of incubation at 2, 6 and 10% rates of incorporation. Inoculated plants wilted and died after the second week without amendment but survival was 90% and 100% from 6% and 10% amendments (Fig. 5). Incorporation of green manure in soil effectively controlled bacterial wilt in the greenhouse.

We are now aiming our research to integrate progress in the development of the host resistance in the Asian region (Opeña et al.1990) with approaches involving biological control and the use of amendments.

Possibilities of Biological Management of Potato Bacterial Wilt with Strains of *Bacillus* sp., *B. subtilis*, *Pseudomonas fluorescens* and Actinomycetes

G.S. Shekhawat, S.K. Chakrabarti, V. Kishore, V. Sunaina and Ashok V. Gadewar*

Abstract

Two strains of *Bacillus* spp., four of *B. subtilis*, three of *Pseudomonas fluorescens* and one actinomycete were tested for management of potato bacterial wilt under glasshouse and field conditions. Isolates of *Bacillus* sp. were most promising. In a glasshouse trial, an isolate of *Bacillus* sp. (SI) reduced wilt by 71%, while in the field isolates S1, S4, BSN1 and BSN2 reduced wilt by 52, 62, 79 and 79%, respectively, from that of the check. They also increased yield by 49–90%. Isolates of *B. subtilis* were not effective in controlling bacterial wilt in either glasshouse or field tests. *P. fluorescens* isolates PF1 and PF2 reduced wilt incidence by 43 and 51%, respectively, in trials in the glasshouse, and by 66 and 75% in the field. An actinomycete isolate was also promising and reduced wilt by 79% under field conditions. In vitro inhibition of *P. solanacearum* did not reflect the potential of an antagonist in glasshouse or field tests.

PSEUDOMONAS solanacearum causes a lethal wilt disease in crops such as potato, tomato, brinjal, chillies, ginger, peanut and banana and in many other plant species (Kelman 1953). In India it is known to infect 114 plant species with or without symptoms and it occurs in moderate to severe form in the northeastern, northern and southern hills, the eastern plains, and the central, eastern and Deccan plateau (Shekhawat et al. 1992). The diverse host range and pathogen variability makes this disease difficult to control. Success in management of potato bacterial wilt has been achieved by agronomic practices (Shekhawat et al. 1990) and to some extent by resistant cultivars (Schmiediche 1986). Breeding for resistance is handicapped by its complex interactions with soil temperature, nematode population (French and De Lindo 1982; Suatmadji 1986), latent infection (Granada 1988) and the presence of highly virulent tropical strains of the pathogen (Jenkins and Nesmith 1976). Biological control strategies may provide alternatives for management of bacterial wilt or they may be integrated with other practices for its practical field management. Several organisms including avirulent strains of *P. solanacearum* (Chen 1983; Lee et al.1986; Luo and Wang 1983), fluorescent pseudomonads (Aspiras and Cruz 1986; Kempe and Sequeira 1983), *Bacillus polymyxa* (Aspiras and Cruz 1986) and actinomycetes (Gao et al. 1983) have been tried with variable success for biocontrol of bacterial wilt. In the study reported here, isolates of *Bacillus* spp., *B. subtilis*, *Pseudomonas fluorescens* and actinomycetes were tested over 3 consecutive years for management of potato bacterial wilt both under glasshouse and field conditions.

*Central Potato Research Institute, Shimla 171 001, India.

Materials and Methods

Isolates of *P. solanacearum* and antagonists

Race 1 isolate CSG 40 was used in all glasshouse experiments. Field experiments were conducted in Bhowali (northwestern hills) where races 1 and 3 are prevalent. Strains of *Bacillus* spp., *B. subtilis* and actinomycetes were isolated from potato rhizosphere and those of *P. fluorescens* from rhizospheres of citrus (PFI), rice (PF2) and potato (PF3). All isolates were

identified by Commonwealth Mycological Institute, Kew, England.

Glasshouse experiments

Clay pots 20 cm in diameter were used to plant two eye-pieces of potato cv. Kufri Jyoti (highly susceptible to bacterial wilt) in each pot. After 1 month, plants were inoculated by the stem-stab method (Winstead and Kelman 1952). Plants were removed after complete wilting, and soil was drenched with a bacterial suspension (~10^9 cfu/mL) at the rate of 200 mL/pot to ensure complete infestation.

Aqueous suspensions (~10^9 cfu/mL) of the antagonists were prepared from 48-hour-old cultures grown on nutrient glucose agar (NGA). Potato eye-pieces were removed from sprouted tubers, dipped in suspensions of test organisms, then dried and planted in pots containing *P. solanacearum* infested soil. Five pots each having three treated eye-pieces were used for each test organism. Eye-pieces dipped in water were planted as controls. Observations on wilt incidence and tuber yield at harvest were recorded. The trial was repeated for three consecutive years.

Field experiments

Before planting field trials in Bhowali, soil contained about 10^5–10^7 cfu/g of soil based on population counts. The trial was conducted in a randomised block design with 6 × 2 m plot sizes and four replications per treatment. Plots were fertilised with 120:100:100 kg of $N:P_2O_5:K_2O$ per ha. Tubers were treated with antagonists as described for the glasshouse experiment. Eye-pieces dipped in water were used as controls. Incidence of bacterial wilt was recorded when the crop was 90 days old. At harvest, tuber yield per plot was recorded. This trial was also repeated for three consecutive years.

In vitro inhibition study. For testing in vitro antagonism between *P. solanacearum* and test antagonists, nutrient glucose agar plates dried for 5 days at room temperature were seeded with isolate CSG 40 by evenly spreading 0.1 mL of suspension (~ 10^9 cfu/mL). Each test antagonist was spotted at four different sites in a single plate. Average diameter of the four inhibition zones after 72 hours incubation at 30°C was used as a measure of antagonism.

Results

Considerable variation occurred in the reduction of wilt incidence and yield with each antagonist (Tables 1 and 2). In the glasshouse trial *Bacillus* spp. (S1) reduced wilt by an average of 72% from that in the control and its performance was consistent over three years. S1 also increased yields by an average of 34%. *P. fluorescens* PF1 and PF2 were also effective, reducing wilt by averages of 43 and 51%, respectively (Table 1). *B. subtilis* isolates were less effective in reducing wilt incidence. However, isolates BS2 and BS3 increased yield by 118 and 110%, respectively, over the control.

In field trials, isolates of *Bacillus* spp. (S1, S4, BSN1, BSN2) and *P. fluorescens* (PF1, PF2) were promising but those of *B. subtilis* were less effective (Table 2). Two isolates of *Bacillus* spp. (BSN1 and BSN2) reduced wilt incidence by about 79% and

increased yield by 85-90% from that of the control (Table 2). The actinomycete isolate included in the field trial was also promising, reducing wilt by 79% and increasing yield by 69%. However, 73% of the tubers rotted (data not included). Performance of *Bacillus* spp., *Pseudomonas fluorescens* (PF1) and the actinomycete was consistent over the 3 years of field trials.

Isolates of *Bacillus* spp. (S1 and S4), *B. subtilis* (BS 1 and BS2) and *P. fluorescens* (PF 1 and PF2) were all inhibitory to *P. solanacearum* in vitro (Fig. 1). *Bacillus* spp. isolate S4 had the greatest inhibition zone. This isolate performed well in the field, but was less effective in the glasshouse study. Both the species of *B. subtilis* (BS1 and BS2) were inhibitory to *P. solanacearum* in vitro but were less effective in reducing wilt under glasshouse conditions or in the field (Fig.1). Isolates of *P. fluorescens* were inhibitory to *P. solanacearum* in vitro as well as being efficient in reducing bacterial wilt incidence.

Discussion

The S1 isolate of *Bacillus* spp. was most promising under glasshouse conditions. Isolates of *Bacillus* spp. (S1, S4, BSN1 and BSN2) were also promising under

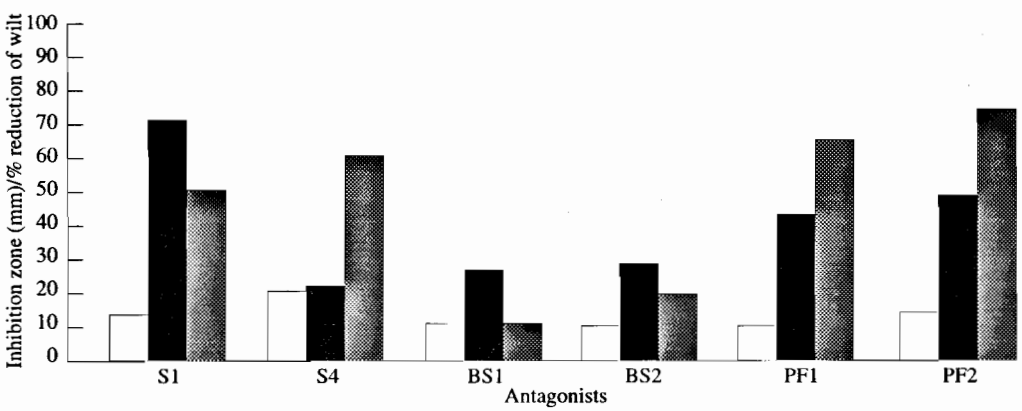

Fig. 1. In vitro inhibition of *Pseudomonas solanacearum* and average percentage wilt reduction by different antagonists. (Note: S1 and S2 are *Bacillus* spp., BS1 and BS2 are *Bacillus sublilis*, PF1 and PF2 are *Pseudomons fluorescens.*) Inhibition zone □; Glasshouse ■; Field ■.

field conditions. *Bacillus* spp. are omnipresent in soil and are most promising in combating soilborne pathogens (Jensen et al. 1986). Their endospores have high thermal tolerance which enables them to survive at extreme temperatures. Relative ease of maintenance in culture and mass multiplication, and stability of spores under adverse conditions, make them ideal biocontrol agents for large-scale use, but more information is needed on why there are not concomitant increases in potato yield. It may be necessary to add plant growth-promoting rhizobacteria in combination with these antagonists for better yields.

Isolates of *B. subtilis* were not effective against potato bacterial wilt under either glasshouse or field conditions. Two isolates of *B. subtilis* (BS2 and BS3) increased yield by more than 100% over the control in the glasshouse trial. The same two organisms, however, increased yield by only 28–32% under field conditions. Reasons for this variation are not known. However, the present isolates of *B. subtilis* were less promising biocontrol agents for potato bacterial wilt.

P. fluorescens (PF1 and PF2) was effective in reducing wilt incidence in both glasshouse and field conditions. They also increased yield by 71–72% under field conditions. Strains of *P. fluorescens* have been reported to increase potato yields in field plots (Burr et al. 1978). They also grow rapidly and colonise potato roots (Aspiras and Cruz 1986). The beneficial attributes of these antagosists are their direct inhibitory effect on the pathogen, their ability to grow rapidly, and to colonise potato root systems and their ability to enhance growth of potato plants (Kloepper et al. 1980).

In vitro inhibition studies may provide preliminary clues to select microbial antagonists against *P. solanacearum*. However, they do not reflect the potential of particular antagonists under field conditions. Isolates of *B. subtilis* and *Bacillus* spp. (S4), for example, had the greatest inhibition zones in vitro but were not promising under glasshouse conditions.

New and Current Reports

Effect of Seedling Preparation, Soil Amendment and Varietal Inheritance on the Incidence of Bacterial Wilt of Tomato

P. Sirithorn, S. Ruaysoongnern and K. Hanmungtham*

Abstract

Soil amendments and resistant varieties have been used to control bacterial wilt of tomato caused by *Pseudomonas solanacearum*. This study investigated control measures by amending infested soil with bagasse and K_2SO_4 alone or in combination with weekly spraying of tomato cultivars VF-134 (susceptible) and L-1 (resistant) with 20-20-20 foliar fertiliser. Survival percentages were recorded weekly. Varietal differences were more important in control than the use of amendments with or without the application of foliar fertiliser.

BACTERIAL wilt of tomato caused by *Pseudomonas solanacearum* is a worldwide threat to tomato production including that in the northeast of Thailand. Currently, this area produces about half of Thailand's total production. Without practicable control measures, production is likely to fall, and costs of production per unit output to rise, due to yield losses and/or the restriction of the suitable production areas. During the past decade there have thus been many studies to find suitable control measures. Wongkaew et al. (1984), for example, verified differences in resistance among nine varieties, reporting that tomato cvs. L-1 and 10-4-3e survived longer than other varieties. Dittapongpitch and Paripunang (1985) further tested cv. L-1 during three successive planting times: wet season, late wet season and dry season. They found that L-1 tomato consistently showed a high degree of resistance to the disease. Wongkaew et al. (1984) also reported that application of bagasse and a high rate of K_2SO_4 (11g/kg of potting mixture) could improve the percentage survival of tomato seedlings. However, after the seedling stage, surviving plants showed various nutritional deficiencies. The result highlighted the potential of these treatments for reducing the severity of the disease if nutritional problems were also addressed. The objective of the study reported here was thus to determine the most effective control measure among the treatments mentioned and whether a combination of them would be effective in controlling bacterial wilt in tomato seedlings with enhanced nutrition.

*Faculty of Agriculture, Khon Kaen University, Khon Kaen 40002, Thailand.

Materials and Methods

The experiment was conducted in a 3×2 split plot design with four replications. Three main plots were: 1. soil infested with *P. solanacearum* as control (T. 1); 2. soil infested with *P. solanacearum* plus bagasse and K_2SO_4 at 11 g/kg of mixture (T. 2); and 3. as for (2) but with seedlings prepared separately and sprayed weekly with 20-20-20 foliar fertiliser (T. 3). Two subplots were tomato cultivars VF-134 (susceptible as check) and L-1 (resistant). Twenty-five-day-old seedlings were transplanted in cement blocks ($1.20 \times 0.6 \times 4$ m^3) with alternate rows between the two varieties.

Survival percentages of tomato plants in each treatment were recorded weekly for 7 weeks (Table 1).

Results and Discussion

Disease development is illustrated in Figure 1. Survival percentages of cv. VF-134 decreased sharply at week 5, while survival of L-1 remained the same for at least 4 weeks in soil amended with bagasse and

Table 1. Percentage survival of two cultivars of tomato under different types of treatment for control of bacterial wilt 7 weeks after transplanting.

Treatment[a]	Survival (%)		
	VF-134	L-1	Average
T. 1	10.0	95.0	52.5 NS[b]
T. 2	11.7	78.4	45.05NS
T. 3	5.0	93.4	49.20NS
Average	8.9	88.9[c]	

[a]T.1 = soil infested with *P. solanacearum*, T.2 = soil infested with *P. solanacearum* plus bagasse and K_2SO_4 at 11g/kg, and T.3 = same as T.2 but seedlings were sprayed weekly with 20-20-20 foliar fertiliser prior to transplanting.
[b]No significant difference.
[c]Highly significant difference.

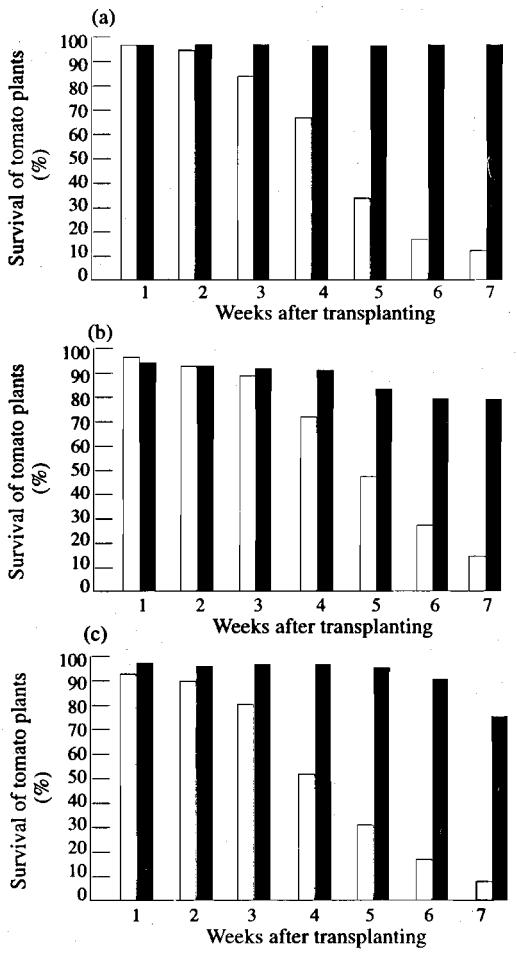

Fig. 1. Percent survival of tomato cultivars; VF 134 □ and L-1 ■ under (a) soil infested with *P. solanacearum*, (b) soil infested with *P. solanacearum* plus bagasse and K_2SO_4 at 11 g/kg, and (c)same as (b) but seedlings were sprayed weekly with 20-20-20 foliar fertiliser prior to transplanting.

K_2SO_4. Nevertheless, control plots supported better survival than the amended soil, particularly during weeks 5–7. Statistical analysis for week 7 data indicated that the varietal factor was more important than the effect of soil amendment or seedling preparation.

The conclusion can therefore be drawn that inheritance of resistance in L-1 cultivar plays a significant role in controlling the incidence of bacterial wilt. Since a high degree of variability of *P. solanacearum* has been documented, trials in farmers' fields are necessary to confirm the results by both larger plant population and area coverage. Moreover, soil types which promote the pathogen would also affect disease severity at individual locations, as suggested by Wongkaew and Dittapongpitch (1983). Therefore, field tests with consideration of soil characteristics are advisable.

Bacterial Wilt in Malaysia: Hosts, Disease Incidence and Geographical Distribution

H. Abdullah*

Abstract

Bacterial wilt caused by *Pseudomonas solanacearum* is the most important bacterial disease of a number of crop plants in Malaysia. The disease is widespread and has been recognised as a common disease of economically important hosts such as brinjal (*Solanum melongena*), chilli (*Capsicum annuum*), ginger (*Zingiber officinale*), groundnut (*Arachis hypogaea*), tobacco (*Nicotiana tabacum*) and tomato (*Lycopersicon esculentum*). However, the extent of damage due to the disease on these hosts, with the exception of tobacco, has not been satisfactorily documented. To date *P. solanacearum* has been reported and/or observed on 43 plant species which include five new hosts of the pathogen in Malaysia. A study to determine the relationship of the environmental conditions in Malaysia and incidence of the disease indicated that the disease can be found throughout the year infecting either crop plants or weeds. The disease also occurred on plants grown in many types of mineral soils (clay, loam and sand) and organic soils (muck and peat). Most incidences of the disease were observed in the lowlands, but the disease has also been found in the highlands (1545 m above mean sea level).

MALAYSIA has a tropical climate characterised by uniform temperatures, high humidities and copious rainfall. Bacterial wilt caused by *Pseudomonas solanacearum* E.F. Smith is the most important bacterial disease of a number of crop plants in Malaysia. Major economic hosts of the pathogen are tomato, (*Lycopersicon esculentum* Mill.), tobacco (*Nicotiana tabacum* L.), brinjal (*Solanum melongena* L.), chilli (*Capsicum annuum* L.), groundnut (*Arachis hypogaea* L.) and ginger (*Zingiber officinale* Rosc.). Introduction of susceptible new crops and/ or new varieties has contributed to the increased incidence of the disease.

Occurrence and Economic Significance

Bacterial wilt was first reported in Peninsular Malaysia in 1910 (Bancroft 1910), on potato and tomato. In 1949 (Burnett, unpublished data) reported widespread occurrence of bacterial wilt on tomato, brinjal, marigold (*Tagetes erecta* L.) zinnia, (*Zinnia elegans* Jacq.) groundnut and cowpea (*Vigna sinensis* L.). The disease has since been reported on a wide range of crops, weeds and ornamentals (Table 1). Five recent new records of the disease are on green gram (*Phaseolus aureus* Roxb.), on a fodder crop, *Sesbania rostrata* Bremek, and on three weed hosts viz., *Erechtites hieracifolia* Rafin., *Hyptis suaveolens* Poit. and *Stachytarpheta indica* Vahl. (Abdullah, unpublished data).

Choong (1967) observed that bacterial wilt incidence was low when tomatoes were first planted in Batu Pahat, Johore, but increased to high levels in second and subsequent plantings, leading to the abandonment or discontinuation of the susceptible crop. Graham and Yap (1976) and Graham et al. (1977) considered bacterial wilt to be the most serious factor limiting commercial production of tomato in the lowlands, so that tomato cultivation is currently confined mainly to high altitude farms in the Cameron Highlands. This includes areas around Tanah Rata, Brinchang, Mensum and Kea Farm. Lower altitude areas surrounding the Cameron Highlands suffer from severe bacterial wilt. Bacterial wilt was first reported to cause severe damage to ginger in the early 1970s, especially in areas such as Raub in Pahang and Morib in Selangor (Lum 1973). However, estimates of losses due to the disease are not available.

[a]Unconfirmed incidence

The disease affects mainly vegetables, which are normally grown on a small scale; thus any incidences or outbreaks of the disease normally go unrecorded. Except for tobacco, there is little information on the extent of the disease on various crops. Yusop (1985) found that 48% of the tobacco plants examined in Bachok, Kelantan were infected with bacterial wilt. In another study, it was found that the severity of bacterial wilt on tobacco varied with location. Field evaluation in Kampung, Badak and Bachok in Kelantan indicated that 44% of the diseased plants were infected with bacterial wilt while at another location, Telong, Bachok, only 2% of the plants had bacterial wilt. The researchers concluded that, under normal conditions (not epiphytotic), a 10% loss of plant counts could be expected as a result of all diseases. This was said to be substantial compared with the value of the crop, which amounts to M$115 million. Thus, assuming an average loss of 2–3% due to bacterial wilt, this would add up to M$2.3–3.45 million total loss of income per crop to the farmer.

Distribution of Bacterial Wilt in Relation to Weather in Malaysia

In a study of the distribution of bacterial wilt in Malaysia, the disease was observed in several localities representing the northern, central and southern regions of Peninsular Malaysia, and East Malaysia (Abdullah 1992). Though the disease was observed mainly in the lowlands where the mean air temperature was in the range of 25–28°C, with mean maximum of 31–33°C and mean minimum of 21–23°C, it was also found in the Cameron Highland at about 1545 m above sea level and ambient temperatures from 16.0–18.5°C, with a mean maximum of 21.2–22.9°C and mean minimum of 13.7–15.6°C.

Generally, the annual rainfall is high over the whole of Malaysia, although the pattern is seasonal. For example, over the east coast of Peninsular Malaysia, during the North-East Monsoon season the months of November and December have the highest rainfall with mean monthly falls of 600–700 mm (Anon. 1975–1984). February, March and April are the driest months with mean monthy falls of 40–100 mm (Anon. 1975–1984). Thus, on the east coast of the peninsula, groundnut and tobacco are normally grown from January–April with harvest from May–August. These are the drier months of the year, when conditions are less conducive to bacterial wilt development. However, even under these conditions, bacterial wilt can be serious in certain localities.

Many researchers have observed higher incidences of bacterial wilt when soil moisture is high (Hingorani et al. 1956; Sabet and Barakat 1971; Abdullah et al. 1983). In a study of the performance of local tomato varieties against bacterial wilt, Ho (1988) also found that high rainfall, especially towards the middle and end of the growing season, favoured high disease incidence. However, the disease has been observed and the pathogen isolated thoughout the year, either from infected crop plants or weeds or both, at the farm of Universiti Pertanian Malaysia (UPM) (Abdullah 1988).

Since *P. solanacearum* is a soilborne organism, the soil climate is an important factor in its survival and subsequent infection of hosts and disease development. Todorov (1980), in a study of soil temperature in Malaysia found that the mean annual soil temperatures in the northern, central and southern parts of the peninsula are 30–31°C, 29–30°C and 28–29°C, respectively. Thus, soil temperatures in Malaysia are conducive to disease development. Biovars 3 and 4 have been reported to be the most prevalent biovars in the country (Abdullah 1983b).

Distribution of Bacterial Wilt According to Soil Type

In a study of the distribution of bacterial wilt, Abdullah (1988) isolated *P. solanacearum* from infected plants grown on organic soils and on light, heavy and intermediate types of mineral soils (Table 2). For example, bacterial wilt was found on tobacco grown in sandy and loamy sand. Light sandy soils have been widely used for tobacco production on the east coast (Trengganu) of Peninsular Malaysia. Incidences of bacterial wilt of chilli, tomato, ginger, French bean, groundnut, tobacco and brinjal, grown in clay soils (soils with more than 40% clay) were common. Generally, tomato was the crop most severely affected, while in other crops the severity of disease varied with locality. Organic soils (soils with more than 65% organic matter) have been widely used for cultivation of a wide range of crop plants. Incidence of the disease in these soils is normally low, except in heavily infested areas and areas where inefficient drainage systems result in high water tables during rainy seasons.

Table 2. Soil types from the northern, central and southern parts of Peninsular Malaysia where *Pseudomonas solanacearum* was isolated from various hosts.

Region	Location	Soil texture	pH	Hosts
Northern	Rengam, Kundar, Akob, Selangor, Tanah Rata	Sandy clay, silty clay, clay	4.5–6.6	Bringal, chilli, croton, ginger, french bean, potato
	Malacca, Goung Chenak Chempaka, Tok Yong	Sandy clay loam, sandy loam, silty clay loam	4.9–6.7	Groundnut, ginger, tobacco, tomato
	Rasau, Radua	Loamy sand, coarse sand	4.6–5.5	Tobacco
Central	Rengam, Bungor, Munchong, Kuantan	Sandy clay, fine sandy clay, clay	5.2–6.9	Chilli, dahlia, corchorus, croton, bladder cherry, euphorbia, chilli, hairy spurge, pig's weed, tobacco, groundnut, ginger, dahlia
	Serdang	Sandy clay loam	4.9–6.7	Cat's whisker, croton, tomato, winged bean, white weed
	–	Organic soils	4.2–6.4	Brinjal, cat's whisker, french bean impomea, chilli, winged bean, ginger, tomato
Southern	Selangor	Clay	4.6–6.2	Chilli, brinjal, tomato
	–	Peat, muck	4.7–5.5	Ginger, tomato, brinjal, chilli

Abdullah et al. (1983) found that soil type and moisture levels individually and in combination had a significant effect on the severity of bacterial wilt of groundnut. Disease severity was highest on Munchong series (clay soil), followed by Bungor series (fine sandy clay) and lastly Serdang Colluvium (sandy clay loam).

Status of Bacterial Wilt of Potato in Kenya

S. Ajanga*

Abstract

In Kenya, bacterial wilt of potato caused by *Pseudomonas solanacearum*, is primarily a disease of lower elevation areas, rarely occurring above 2100 m altitude. Seed production and certification are done in high elevation zones. Certified seed is expensive and used by only a small proportion of farmers in Kenya. All the varieties being multiplied and supplied as certified seed are susceptible to bacterial wilt. A two-year crop rotation involving potato and pasture is effective in controlling bacterial wilt. In the main potato-growing areas farms are small; therefore, farmers find it difficult to follow recommended rotation practices. This, coupled with lack of comprehensive knowledge about management practices among farmers, has led to low crop yields.

In Kenya, the main potato production areas are above 1500 m (Fig. 1). An annual rainfall of more than 1000 mm and altitudes above 1500 m are the main requirements for potential potato cultivation. However, with increasing land pressure in these areas, potato production is moving to lower areas where cultivation potential is limited primarily due to low yields caused by poorly adapted cultivars, high bacterial wilt incidence, and inadequate management of the crop.

Incidence of bacterial wilt of potato caused by *P. solanacearum* is greatest at altitudes between 1520 and 2120 m. The disease rarely occurs at higher altitudes (Nyangeri et al. 1984). At high elevation zones, race 3, biovar 2 is the cause of bacterial wilt. However, at lower elevations, it is not known whether other races exist on potato. In some of these areas, wilt has been observed in other solanaceous plants such as eggplant, *Solanum nigrum*, tomato, and capsicum (Harris 1976).

In higher elevation zones of Kenya where bacterial wilt of potato is caused by race 3, control by the combined use of certified seed, resistant cultivars, and fallowing and crop rotation for eradication is recommended. A two-year pasture rotation has been found to reduce bacterial wilt. However, land pressure may not allow this type of rotation in most potato-growing areas. Also, resistant or tolerant cultivars are lacking, certified seed is expensive or unavailable, and farmers lack comprehensive knowledge on the control of bacterial wilt.

Production of certified seed is carried out in areas at mid elevation. There have been cases documented where certified potato seed planted at lower elevations produced wilted plants (Nyangeri et al. 1984). This means either that the lower areas were contaminated by *P. solanacearum* or that some of the seed tubers were latently infected, which could be one of the major factors in the spread of bacterial wilt to lower areas.

Currently, only a small portion of farmers use certified seed. The average demand for certified seed by farmers is 12 000 bags/year, whereas the total area under potato cropping is estimated to be 75000–100000 ha. Most farmers grow their own seed or purchase it from local markets. Such seed can be latently infected and a major source of contamination to areas free of infestation. However, there is now an upward trend in demand for certified seed due to increased awareness by farmers of latent infection.

The Agricultural Development Corporation (ADC) is responsible for certified seed production in Kenya and tries to produce enough seed to meet demand. There have been occasions when 75% of the seed produced was discarded. In 1987, approximately 10000 bags were discarded. One factor that influences seed sales is low prices for market potatoes. The popular cultivars being multiplied are Desiree, B53,

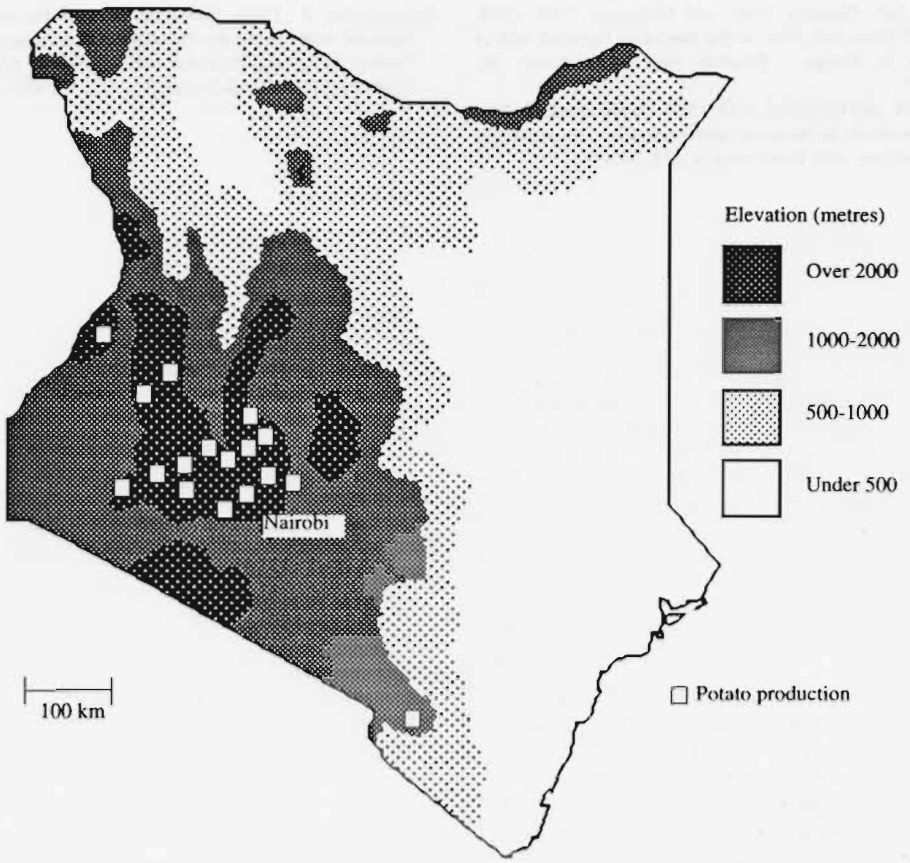

Fig. 1. Potato production areas in Kenya.

Dutch Robjn, Annet, Romano, Pimpernel, Kenya Dhamana, and Kenya Baraka.

Research has been carried out in the areas of tolerance or resistance to bacterial wilt. Pot and field experiments of clones that were derived from crosses between *S. phureja* parents—resistant to bacterial wilt—and susceptible parent CIP 720054 (Atzimba) were tried in Kenya. Other clones, most notably CIP 720118, 800212, 800222, 800223 and 800224, were classified as the most tolerant (Ramos and Michieka 1988). Several of these were developed from crosses with *S. phureja* (resistant to *P. solanacearum*) and *S. demissum* (*Phytophthora*-resistant Mexican cultivars) and are known as the BR clones (French 1985; Schmiediche 1986). Of these, only CIP 800224–Kenya Dhamana has been released to farmers. Most cultivars grown in Kenya are susceptible to bacterial wilt.

Considerable attention should be given to local breeding for resistant cultivars and/or acquisition of resistant cultivars from elsewhere for local testing. Cultivars bred for resistance in one area may not sustain that resistance when transferred to Kenya, but evaluation of such cultivars is important. It is understood that the use of tolerant or resistant cultivars alone would not solve the problem, but can be complemented by use of other factors that contribute to lowering inoculum potential, such as rotation, clearing of debris from diseased crop, and removal of other hosts.

Advance of Bacterial Wilt in Bananas in Mexico

L.Z. Fucikovsky and M.O. Santos*

Abstract

Bacterial wilt of bananas (Moko disease) has, until recently, been confined in Mexico to the Tapachula and Villa Flores areas of Chiapas State. In 1991, however, the disease appeared on a banana plantation in the Teapa region of the State of Tabasco on the Gulf of Mexico, affecting some 20 plants. Characterisation of *Pseudomonas solanacearum* strains indicated that all were race 2, biovar 1. Flooding and movement of contaminated plant material could explain how the pathogen was introduced to this new area.

BACTERIAL wilt of banana (Moko disease) has been known to cause serious problems in the Tapachula and Villa Flores regions of Chiapas, which borders on Guatemala, since 1960 (Buddenhagen 1961; Santos 1987). In October 1991 symptoms of this disease were detected in the important banana region of Teapa, Tabasco. This paper reports on a visit to the affected area, and verifies that the causal organism was *Pseudomonas solanacearum.*

Materials and Methods

In October 1991, samples of different parts of diseased five-year-old banana plants with bacterial wilt were received from a banana ranch of approximately 50 ha. The ranch borders on a tributary of the river Grijalva which enters the main stream in the area of the city of Teapa, Tabasco. This tributary often floods, inundating areas of the ranch. Samples of corm, ranchis, pseudostem and fruits were analysed to isolate the causal organism. Bacteria isolated from the vascular system were purified and inoculated on young banana plants in the greenhouse. After the appearance of symptoms, the bacterium was reisolated and characterised in triplicate to biovar using biochemical tests (Hayward 1988).

Results and Discussion

One type of bacterium predominated in all samples received. Isolates from all samples caused wilt on young banana plants in the greenhouse after 9 days. The reisolated bacterium on casaminoacid-peptone-glucose (CPG) medium with tetrazolium chloride (Kelman 1954) produced typical fluidal and coloured colonies similar to known *P. solanacearum* isolates from Chiapas obtained from our collection.

Isolates were Gram-negative, oxidase and catalase positive, produced hypersensitive reaction in tobacco in 24 hours, did not rot potatoes or fluoresce, and did not oxidise maltose, lactose, cellobiose and sucrose. They utilised trehalose, but not mannitol, sorbitol and dulcitol after 15 days. All isolates produced gas from nitrate, although some in larger quantities than others. On the basis of this and its origin from banana, the isolates were identified as *P. solanacearum*, race 2, biovar 1. This is the first report from Mexico of biovar 1 on banana.

The occurrence of this disease in Mexico was first reported in Chiapas in 1960 and now extends to an important banana-producing zone of Tabasco (Fig. 1). Various factors may be responsible for its geographical spread from Chiapas to Tabasco. The bacterium may have been carried in floodwater from the wilderness area between Chiapas and Tabasco. Another possibility is that it arrived by high winds, rain, and insects from Chiapas or the Lake Izabal region in Guatemala, where the disease is known to occur. This possibility seems more remote, because of the distance involved. The most probable means of introduction is human movement of contaminated material into the region.

Control measures were immediately employed in Tabasco, and the diseased plants were eliminated to prevent the spread of the disease to other banana-growing regions.

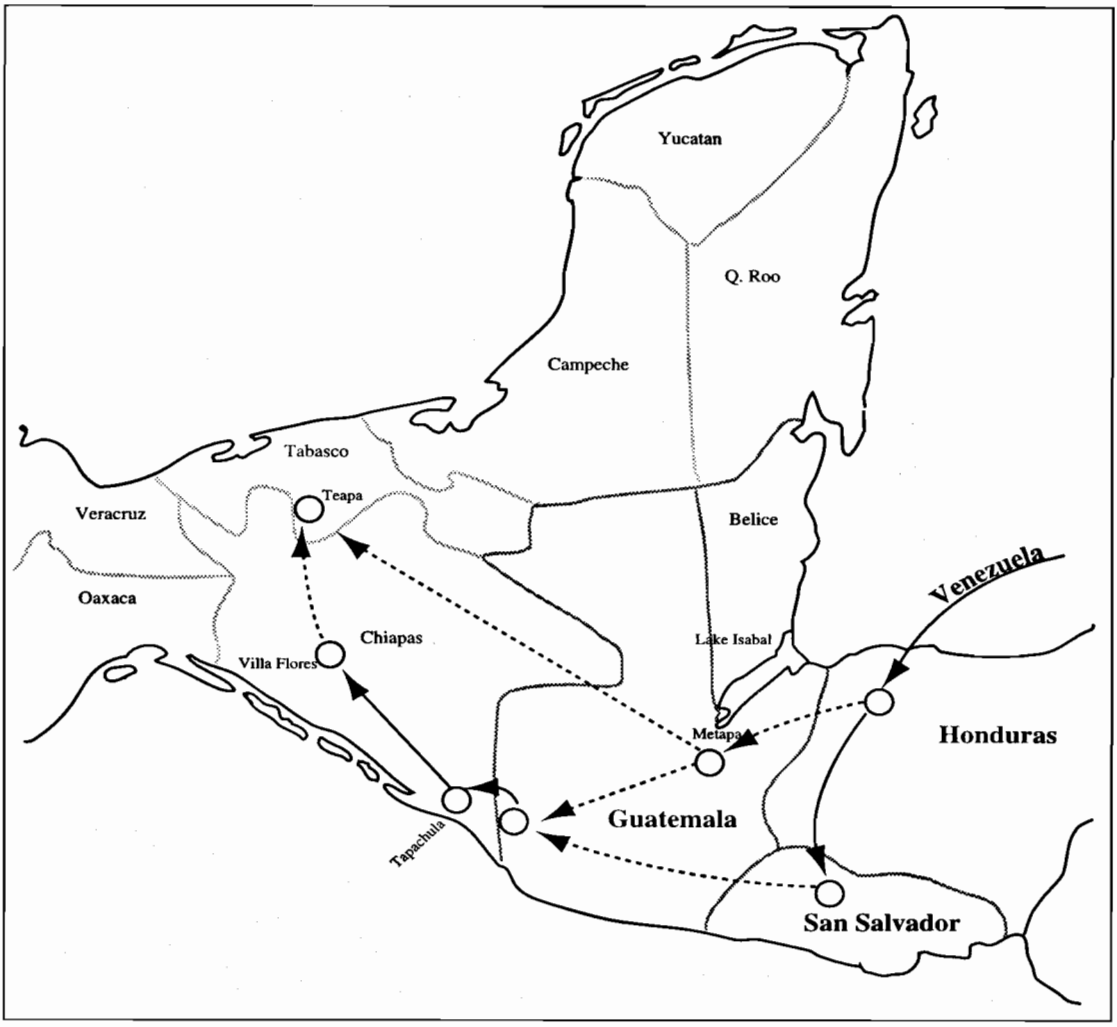

Fig. 1. Advance of Moko on banana from South America to Honduras and San Salvador (→)(after Stover 1972), and its later distribution in Guatemala (Lake Izabal area and surroundings of city of Metapa), (---->). From Guatemala the disease advanced to Mexico to the State of Chiapas, first reported close to the city of Tapachula, later in Villa Flores in 1987 and finally close to the city of Teapa, State of Tabasco in 1991. Areas where Moko disease exists are marked with circles.

Acknowledgments

Sincere thanks are expressed to Ing. Miguel A. Contreras for information on this disease and for sending the material and supporting a visit to the affected area.

Bacterial Wilt Due to *Pseudomonas solanacearum* in Réunion: General Situation and Current Research

J.C. Girard, J.F. Nicole, J.J. Chéron, A.M. Gaubiac, O. Huvier, B. Oudard and H. Suzor*

Abstract

Pseudomonas solanacearum **was isolated from 19 species on Réunion island. Five species (*Allium cepa*, *Euphorbia pulcherrima*, *Kalanchoe blossfeldiana*, *Obetia ficifolia* and *Schinus terebinthifolius*) may be considered as new hosts for *P. solanacearum*. Isolates of the pathogen on the island were: race 1/biovar 1, race 1/biovar 3, and race 3/biovar 2. Crop rotations and, in the case of eggplant, grafting on *Solanum torvum*, have been used by some farmers for control for many years. A few promising varieties of tomato and eggplant have been identified when screening accessions for resistance but their levels of resistance and/or agronomic performances are not sufficient. In the case of hydroponic production, steam and calcium hypochlorite treatments were shown to reduce the incidence of wilt in tomatoes. The influence of abiotic factors on the development of bacterial wilt to different isolates is being investigated, with the aim of promoting to farmers control measures adapted to their local conditions.**

RÉUNION (21°S.,55°30`E) is a volcanic island in the Indian Ocean located 700 km east of Madagascar and 200 km south west of Mauritius. Two main seasons occur: a cool, relatively dry season from May–October (mean temperature of the coldest month 19°–21°C at sea level), and a warm, rainy season (mean temperature of the hottest month 26°–28°C at sea level).

Agriculture is practiced from sea level up to 1700 m elevation. The combined effects of season, climatic conditions (the leeward side of the island is much drier than the windward side) and altitude account for the wide range of crops that can be grown (temperate to tropical), and also for the large number of diseases and pests attacking them. Sugarcane has long been the main crop, but during the last 15 years, cattle breeding and the production of fruit, vegetables and flowers has increased. Among these new crops are several species that are potential hosts for bacterial wilt. Indeed, the incidence of the disease has been increasing annually.

Host Plants and Economic Importance

Pseudomonas solanacearum E.F. Smith has been isolated from 19 plant species belonging to 10 families both mono- and dicotyledons in Réunion (Table 1). Comparison of Table 1 with the list of Bradbury (1986) indicates that 5 species may be considered as new hosts for *Pseudomonas solanacearum*. These are *Allium cepa* L., *Euphorbia pulcherrima* Willd. ex Klotzsch, *Kalanchoe blossfeldiana* (of questionable identity), *Schinus terebinthifolius* Raddi and *Obetia ficifolia* (Poiret) Gaudich, though onion (*A. cepa*) has already been reported as a host in Venezuela (Trujillo et al. 1989).

From an economic point of view, bacterial wilt is a serious problem mainly in solanaceous crops—tomato, potato, eggplant and bell pepper—but occasionally also on géranium rosat (*Pelargonium*×*asperum* Ehrh. ex Willd, grown for its oil used in perfume industry, and on anthurium (*Anthurium andreanum* Linden ex André). In many cases, bacterial wilt makes the cultivation of tomato, eggplant and potato impossible in heavily infested soil, particularly during the warm and humid season (November–April). These crops may also be seriously affected when grown hydroponically,

[a]Uncertain identity.
[b]Isolated from plants wilting after tobacco hypersensitivity tests.

if the growth substrate is infested. On the other hand, bacterial wilt has never been reported from tobacco under field conditions in Réunion and we were unable to transmit the disease to this plant through artificial inoculation with different local strains, although some tobacco plants wilted following hypersensitive tests performed on many leaves (Huvier, unpublished data 1985 ; Oudard, unpublished data 1986).

Pathogen Populations and Geographical Distribution

P. solanacearum strains have been classified into different races on the basis of their host plants (Buddenhagen et al. 1962; Hayward et al. 1967; He et al. 1983) and into different biovars on the basis of their physiological characteristics in culture (Hayward 1964; He et al. 1983).

The first report of *P. solanacearum* in Réunion, appears to be that of Roger (1960) on potato, who also suspected the occurrence of the disease on géranium rosat. Hayward (1964) reported that an isolate from géranium rosat in Réunion in 1961 belonged to biovar 1. Prunier (1967) found that three isolates from Réunion belonged to biovar 3. Isolates from 1980–1987 were all classified as biovars 1, 3, and 4 (Escalant-Tauziet 1983; Huvier, unpublished data; Oudard, unpublished data; Girard 1989), but those considered as biovar 4 were, in fact, biovar 3 strains which oxidise lactose, maltose and cellobiose very slowly. More recently, race 3/biovar 2 was reported in the island for the first time (Suzor, unpublished data 1988).

All isolates of *P. solanacearum* have been found in areas ranging from sea level up to 1700 m elevation, but only a few originated from 200–600 m (Table 2), probably because sugarcane is the predominant crop there.

Of 118 isolates, 10% were biovar 1, 24% were biovar 2, and 67% were biovar 3/race 1. These were found on various crops and host plants throughout the island from sea level up to 1000–1200 m elevation. On the other hand, race 1/biovar 1 strains have been reported from only two areas: a large area on the leeward side of the island between 600–1000 m elevation on géranium rosat, tomato and potato and a small area in the south on géranium rosat. It is to be noted that all the local biovar 1 isolates grow very slowly on different agar media as compared with the biovar 2 and especially biovar 3 isolates.

Race 3/biovar 2 isolates were obtained mainly from potato in a restricted geographical area called 'Plaine des Cafres', from 1200–1700 m elevation (Girard 1989) and in three cases from tomato in the lowlands,

Table 2. Number and percentage of 118 isolates of *P. solanacearum* grouped by altitude of isolation.

Altitude (m)	Number	Percentage
1–199	48	40.7
200–599	8	6.8
600–999	22	18.6
1000–1700	40	33.9

once in a field and twice in hydroponic culture. The recent discovery of race 3/biovar 2 in the main potato-growing area in Réunion may be the result of importation of potato for human consumption from South Africa, where biovar 2 is known to be present (Swanepoel and Young 1988). The occurrence of biovar 2 isolates on tomato under comparatively warm conditions in areas where race 1 is prevalent is not clearly understood.

Control Attempts

Crop rotations are occasionally used, but it is not clear if there is widespread awareness among farmers of the effectiveness of this control technique. Certainly, many farmers discontinue the cultivation of susceptible crops on heavily infested soil merely because they believe it pointless perservering. The most efficient rotations are probably those with sugarcane or pasture, since both are non-host plants and require a long period before harvest. In the case of potato,crop rotations and the use of disease-free seed tubers planted in disease-free soils are recommended by the extension services, but these measures are not always followed by potato growers. It is of note that a small amount of potato seed is produced locally in disease-free areas (over 1000 m elevation on the leeward side of Réunion). Samples of the tubers are analysed by the Plant Protection Service by immunofluorescence following the technique of Janse (1968) before release.

On the windward side of the island, some farmers have traditionally grafted eggplants to the wilt-resistant stock plant *Solanum torvum*, but for various reasons this technique has never been used on a large scale. It is time-consuming and the fruits harvested on grafted plants are said to be bitter.

During the past 10 years, resistant tomato and eggplant varieties from various sources have been tested on Réunion (Girard et al. 1989). However, results have so far been generally disappointing because of insufficient levels of resistance and/or unacceptability of the fruit to the local market.

The introduction of hydroponic culture of tomatoes was in part to escape the problem of soil infestation by *P. solanacearum*. One farmer is now testing the technique in individual containers under both greenhouse and open field conditions. His fields had become so heavily infested with wilt disease that it became impossible to grow even some of the so-called resistant tomato varieties.

Heat and chemical treatments were tried by two farmers using hydroponics because tomato rows had been seriously infected by bacterial wilt. The best results were obtained with a combination of steam and calcium hypochloride treatments. Similarly, anthurium growers rogue infected plants and the symptomless surrounding ones before treating the soil or substrate with calcium hypochloride.

Current Research on *P. solanacearum* in Réunion

Studies of the local populations of *P. solanacearum* and a search for resistant varieties of tomato and eggplant have been the main focus of research on Réunion in recent years. Over 130 tomato varieties of various origins have been screened since 1980, but no definitive results have yet been obtained. The highly-resistant varieties are not accepted on the local market (for instance Caraibo from INRA-Guadeloupe) and those which produce acceptable fruits with high yields are not resistant enough in the event of severe disease pressure (Calinago and Caracoli from INRA-Guadeloupe; Summertaste from Yates; and PT 40/26, PT 41/65, FMTT 23 from AVRDC). Nevertheless, the latter varieties may be useful under moderate infestation pressure, and some farmers have shown interest in growing them. More recently, cooperative trials have been undertaken in several tropical countries (Brazil, Burkina Faso, French Antillies, and Réunion) to study a range of tomato varieties known to be resistant to bacterial wilt when challenged by different populations of the pathogen under various environmental conditions. Some varieties of eggplant bred by INRA-Guadeloupe after crossing *Solanum melongena* and *S. oethiopicum* (Ano et al. 1991) showed a promising level of resistance on Réunion, but improvements in fruit size and local market acceptability are needed.

A research project on the structure and dynamics of *P. solanacearum* populations in Réunion was recently started. It aims to determine how factors such as isolate temperature, soil type, variety, vegetation and biotic or abiotic stress influence the expression of bacterial wilt on potatoes and tomatoes. The overall objective is to formulate control measures adapted to local conditions (soil, climatic conditions, nature and degree of infestation of their plots, etc). Previous experiments (Gaubiac, unpublished data) have indicated differences between isolates in the effect of average temperature on in vitro growth and pathogenicity. The in vitro growth of race 1 was much more influenced by temperature than that of race 3 (Fig. 1). The disease progress curve (wilt index) of tomatoes inoculated with race 1 was similar to that of its in vitro growth, rising with temparature whereas the disease progress curve of the race 3 fell markedly above 20°C (Fig. 2). Moreover, when the two races were mixed and inoculated in a 1/1 ratio at different temperatures, a clear-cut predominance of race 3 in the wilting tomato plants was observed at 15°–20°C, whereas race 1 was more

prevalent at 24° and 30°C (Fig. 3). At 22°–23°C, results were not consistent as variable proportions of wilted plants were invaded by one or other strain. In rare cases the same plant was invaded by both races (Girard 1991).

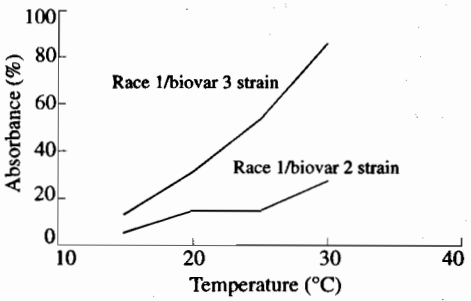

Fig. 1. In vitro growth of two strains of *Pseudomonas solanacearum* at four temperatures after four days.

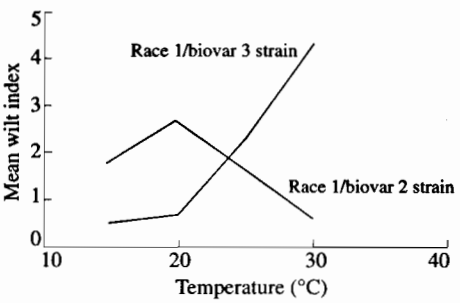

Fig. 2. Mean wilt index of tomatoes inoculated with two strains of *Pseudomonas solanacearum* at four temperatures five days after inoculation. Ratings are the average of 30 tomato plants using the rating scale of Winstead and Kelman (1952), with slight modification.

Conclusions

Although bacterial wilt has been extensively studied around the world for several decades, efficient and complete control measures are not available for many susceptible crops. On Réunion island, the recent intensification of vegetable crop production, in particular solanaceous types, has resulted in a higher incidence of bacterial wilt and increased losses. Varietal resistance has not solved the problem completely, and it may be a long time before highly resistant and high yielding varieties, endowed with other desirable characteristics, are available. Crop rotations with non-host plants are not acceptable to many farmers, particularly if they are

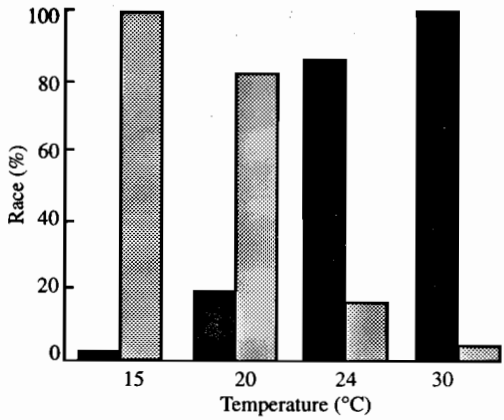

Fig. 3. Percentage of race 1/biovar 3 ■ and race 3/biovar 2 ▨ colonies isolated from 30 wilted tomato plants after inoculation with a mixture of both races (1/1) at four different temperatures.

prolonged, and this accounts for a need for complementary control methods. We hope that, as a result of the intensified research that started in Réunion recently, more appropriate and efficient advice on control of bacterial wilt can be delivered to farmers.

Acknowledgments

We are grateful to AVRDC, CIP, INRA-Guadeloupe, MSIRI, and the Ministry of Agriculture in Mauritius for the supply of tomato, potato and eggplant resistant cultivars; and to CIP and Rothamsted Experimental Station for sending *P. solanacearum* reference strains. Our thanks go to Mr S. Saumtally from MSIRI for revising this communication.

Interaction of *Pseudomonas solanacearum* and *Phytophthora capsici* on Peppers

G.L. Hartman, Y.H. Huang and W.F. Hong*

Abstract

Bacterial wilt caused by *Pseudomonas solanacearum*, and *Phytophthora blight* caused by *Phytophthora capsici*, are important soilborne diseases of peppers (*Capsicum* spp.). Plant mortality of peppers from 11 fields (about 22 000 plants) in Linnei township in Yunlin County, Taiwan ranged from 5–95% with a mean of 28%. Both *P. capsici* and *P. solanacearum* were suspected as being causal agents alone or in combination; however, the primary symptoms observed were wilt with vascular browning indicating that *P. solanacearum* was the primary pathogen. *P. solanacearum* was isolated directly from field-infected tissue on a selective medium. *P. capsici* was isolated from infected stems of 30-day-old plants (variety 'Blue Star') that had been transplanted into infested Linnei soil in pots. Several experiments were conducted to evaluate the interaction of these two pathogens by soil drench inoculation alone or, in combination, by delayed application or reduced inoculum concentrations of *P. capsici*, and by using resistant hosts. Applied alone, *P. capsici* caused higher plant mortality in a shorter time than did *P. solanacearum*. *P. solanacearum* in combination with low doses of *P. capsici* caused 62% greater plant mortality than *P. capsici* at low doses. Mortality of plants increased when *P. capsici* was inoculated after *P. solanacearum* compared with inoculating with *P. solanacearum* alone. In another experiment using resistant hosts, values for the area under the disease progress curve (AUDPC) were similar for cv. PBC 066 whether it was inoculated with *P. solanacearum* alone or in combination with *P. capsici*. However, AUDPC values increased for PI 201234 with the addition of *P. solanacearum*. This appears to be the first report of an interaction beween these two soilborne pathogens, which overlap in their ecologies and host range.

BACTERIAL wilt caused by *Pseudomonas solanacearum* E.F. Smith, and Phytophthora blight caused by *Phytophthora capsici* Leon. are soilborne diseases of peppers (*Capsicum* spp.). *P. solanacearum* normally causes a vascular wilt and infects a wide range of hosts (Kelman 1953; Hayward 1993). In much of the Asian tropics and subtropics, plant species belonging to the solanaceous family, including eggplant, pepper, and tomato, are affected by race 1, biovar 3 and 4. *P. capsici* causes basal stem blight or collar rot of peppers (Leonian 1922).

There are many reports about the interaction of *P. solanacearum* with other microorganisms, especially plant parasitic nematodes (Libman et al. 1964), but there appear to be no reports of *P. solanacearum* interacting with *P. capsici*. Both these pathogens are likely to occur in moist soil and at high ambient and soil temperatures, and it seems feasible that the two organisms share similar soil niches.

The objectives of this research were to: 1. isolate the causal organism(s) from pepper plants in fields where plant mortality was excessive; and 2. determine under controlled conditions what kind of interaction occurred between *P. solanacearum* and *P. capsici* when inoculated on pepper seedlings.

Materials and Methods

Field observations

Eleven fields of pepper in Linnei township, Yunlin County, Taiwan, representing approximately 22000 plants were assessed for plant mortality at fruit-setting

*Asian Vegetable Research and Development Center, Shanhua, Tainan, Taiwan, 741, Republic of China.

by counting the total number of dead plants in the population. Soil and plant samples were collected for isolation of pathogens. *P. solanacearum* was isolated by macerating tissue with distilled water and streaking on a modified selective medium (SM-1) (Chang and Hsu 1988). *P. capsici* was isolated by planting 30-day-old plants (cultivar Blue Star) in infested soil sampled from the Linnei fields. Five days after inoculation, stem pieces from blighted plants were surface sterilised, rinsed, and plated on potato dextrose agar (PDA).

Inoculum preparation

A strain of *P. solanacearum* coded as Pss 71 isolated from infected pepper plants at Linnei was used in all the experiments. The strain was isolated from pepper on SM-1 medium, purified on tetrazolium chloride (TTC) medium (Kelman 1954) by selecting fluidal wild-type colonies, stored in water and increased on 523 medium (Kado and Heskett 1970) for 24 hours at 32°C. Cell suspensions were adjusted to 10^8 cfu/mL using a spectrophotometer at 600 nm with an optical density of 0.3.

Isolate Pc13A of *P. capsici* isolated from infected plants (Blue Star) planted in infested Linnei soil was used in all experiments. It was isolated from infected pepper stems and stored on PDA. Inoculum was increased on V8 agar (Miller 1955) using methods previously described (Hartman and Huang 1993). All suspensions for each experiment were adjusted to 1×10^4 zoospores/mL unless otherwise stated.

Inoculum was applied in suspension by drenching soil using 1.2 L per flat (48×33×10 cm) or by adding 30 mL of suspension when 5 cm diameter pots were used. In all cases, seeds were sown in sterile potting mix.

Preliminary test

Pepper seeds collected from fruits of an unknown variety in the Linnei fields were planted in 5 cm diameter pots containing a sterile soil mix and held in the greenhouse. When seedlings were 30-days-old inoculum was drenched into the soil. The following five treatments were used to investigate the interaction of the two pathogens: 1. *P. solanacearum* alone; 2. *P. capsici* alone(1×10^2 zoospores/mL); 3. *P. capsici* alone (1×10^4 zoospores/mL); 4. *P. solanacearum* and *P. capsici* (1×10^2 zoospores/mL); and 5. *P. solanacearum* and *P. capsici* (1×10^4 zoospores/mL).

Each treatment had 12 plants. There were no replications. Plant mortality was recorded daily for 17 days after inoculation. Data were converted to percentages by: (number of dead plants/total number of plants) × 100.

Advanced test

Seeds of an AVRDC plant breeding line (PBC 243) were sown in flats and were either not inoculated or inoculated when 30-days-old with one of the following: 1. *P. solanacearum* alone; 2. *P. solanacearum* and *P. capsici* (1×10^2 zoospores/mL); 3. *P. solanacearum* and *P. capsici* (5×10^2 zoospores/mL); 4. *P. solanacearum* and *P. capsici* (1×10^3 zoospores/mL); 5. *P. capsici* (1×10^2 zoospores/mL); 6. *P. capsici* (5×10^2 zoo-spores/mL); and 7. *P. capsici* (1×10^3 zoospores/mL). Soil was cut with a knife between the rows to approximately 6 cm. There were two replications for each treatment.

Interactions using resistant/susceptible hosts

Seeds of cultivars, Sunny Star, Queen Star; AVRDC lines PBC 142A, PBC 243, PBC 066; and PI 201234 were planted in flats in a sterilised soil mix. Forty-day-old seedlings were either not inoculated or inoculated as follows: 1. *P. solanacearum* alone; 2. *P. capsici* alone; 3. *P. solanacearum* and *P. capsici*; 4. *P. solanacearum* and *P. capsici* delayed by 3 days; 5. *P. solanacearum* and *P. capsici* delayed by 7 days; 6. *P. solanacearum* and *P. capsici* delayed by 10 days; and 7. *P. solanacearum* and *P. capsici* delayed by 14 days. Soil was cut between the rows with a knife to approximately 6 cm before drenching the soil with inoculum. Plants were rated for mortality at 7, 10, 14, 17 and 21 days after inoculation. Area under the disease progress (AUDPC) was calculated (Shaner and Finney 1977).

The experiment was a split plot with the main plots as pepper entries and the subplot as inoculation treatments. There were five plants and three replications for each entry and inoculation combination.

Results

Field observations

Pepper mortality ranged from 5–95% with a mean of 28% over all 11 fields. Both *P. capsici* and *P. solanacearum* were isolated, and vascular wilt and stem blight were observed in the field individually, although the vast majority of wilted plants had vascular discoloration indicating that the primary cause in this field may have been *P. solanacearum*. Other wilt pathogens, including *Fusarium* and *Verticillium*, were not isolated.

Preliminary experiment

Three days after inoculation, plants that were inoculated with high doses of *P. capsici*, and one with a low dose of *P. capsici* in combination with *P. solanacearum*, had 100% mortality (Fig. 1). Plants inoculated with *P. solanacearum* alone had 84% mortality after 17 days compared with the 38% mortality caused by *P. capsici* alone at a low dose. The increase in plant mortality when *P. solanacearum* was added to *P. capsici* at a low dose was 62% higher at 17 days after inoculation.

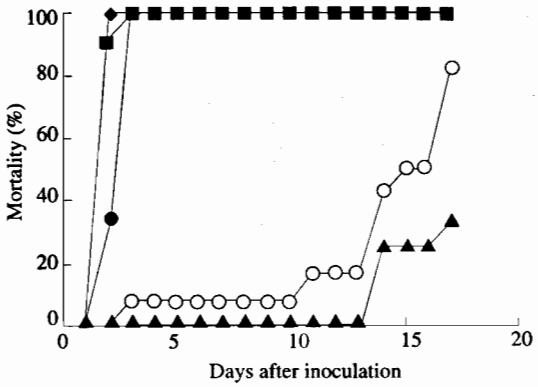

Fig. 1. Pepper mortality after inoculating plants with *Pseudomonas solanacearum* (Ps) and *Phytophthora capsici* (Pc) at two concentrations (1×10^4 and 1×10^2 zoospores/mL). Ps + Pc-4 ◆ (treatment 5); Ps + Pc-2 ■ (treatment 4); Pc-4 ● (treatment 3); Pc-2 ▲ (treatment 2); and Ps ○ (treatment 1).

Advanced test

Treatments using *P. capsici* alone (treatments 5–7) did not produce any blight for the first 11 days. One treatment had caused a small degree of blight (5%) at 14 days after inoculation. These three treatments were not used in the data analysis.

Plants inoculated with *P. solanacearum* alone had significantly more wilt at 7 days after inoculation than with *P. capsici*, but were equal to *P. capsici* at 14 days after inoculation (Fig. 2a). Phytophthora blight was greater than that in plants inoculated with *P. capsici* alone, and also increased as higher doses of *P. capsici* were applied (Fig. 2b).

Interactions using resistant/susceptible hosts

Pepper lines, inoculation treatments, and their interactions were all highly significant ($P < 0.05$). Treatments of *P. capsici* alone, and in combination with *P. solanacearum* either at the same time or when delayed by only 3 days, had the highest AUDPC values (Table 1). Both pathogens added together usually caused more blight than wilt symptoms, but as the *P. capsici* inoculations were delayed, more wilt symptoms occurred. The lowest AUDPC values were obtained from PI 201234 which is highly resistant to *P. capsici* (Table 2).

Table 1. Area under disease progress curve (AUDPC) for the means of six pepper lines either inoculated with *Pseudomonas solanacearum* (Ps) or *Phytophthora capsici* (Pc) alone or in combination.

Discussion

Interactions of *P. solanacearum* with other pathogens, especially nematodes have been documented, but this is the first report of an interaction of *P. solanacearum* and *P. capsici*.

The two pathogens both cause wilt diseases, which under close field examination could be distinguished. *P.capsici* caused a collar rot or a stem lesion with dark brown stem discoloration extending upward from the soil line, while *P. solanacearum* caused vascular discoloration without external discoloration on the stem.

In this study, *P. capsici* was more aggressive than *P. solanacearum* and inital wilting and blight occurred within 2–3 days after inoculation at high doses, regardless of whether the plants had also been inoculated with *P. solanacearum*. When *P. solanacearum* was inoculated alone, plants started to wilt only after 10 days.

Also found was that bacterial wilt did not increase when both pathogens were inoculated together even when *P. capsici* was applied at low doses. Addition of *P. solanacearum* did not increase blight when *P. capsici* was inoculated at high doses; however, blight did increase greatly when *P. solanacearum* was added with low doses of *P. capsici*. From these observations, it appears that *P. capsici* has little effect on bacterial wilt levels, but that blight is increased when *P. solanacearum* is added to low inoculum doses of *P. capsici*.

Bacterial Wilt of Tomato in Andaman and Nicobar Islands

C.R. Ramesh and A.K. Bandyopadhyay*

Abstract

The humid tropical climate with a mean year round temperature of 30°C and a variety of soil types are conducive to bacterial wilt in the Andaman and Nicobar islands. The disease incidence ranges from 5–100% in tomato production areas across the islands. The pathogen infects brinjal, chilli, groundnut, potato and tomato plants. Several weed hosts have been recorded as carriers of the pathogen. Although different soil types cropped to tomato are infested, it is absent in the tomato-growing soils of Neil Nicobar islands. Vertical distribution, the effect of pH and other physical factors on the pathogen were studied. Severe incidence of the disease on tomato has made it difficult to grow this crop. However, with the identification of resistant cultivars, tomato cultivation has increased. Of 800 lines screened under sick plot conditions, seven were highly resistant. Incidence of bacterial wilt was lower in rice fallow compared with monocropping of tomato.

THE Andaman and Nicobar Islands comprise a chain of 572 islands, islets and isolated rocks spread in the Bay of Bengal at a distance of about 1200 km from the east coast of the Indian subcontinent. Of the 306 islands, only 188 have been named. The Andaman group, with 278 islands, forms the northern part of the chain. The Nicobar group is separated from the main group by 160 km of ocean, and has 28 islands. The major land mass is occupied by North, Middle and South Andaman Islands which are separated from each other by narrow channels. The maximum width of the islands is 50 km.

The islands make up two concentric arcs: an outer (western) sedimentary arc comprising Major Islands of the Andamans and the Nicobar extending to the south east forming Indonesian Orogenic belt; and an inner (eastern) volcanic arc appearing above sea level as the conical volcanoes of Narcondum and Barren Islands.

The climate of these islands is typically equatorial (warm, humid tropical). The islands receive both southwest and northeast monsoons from May through December. Normal annual rainfall is around 3000 mm. Average relative humidity ranges from 68–86%, while the daily mean temperature ranges from 21.8°C minimum to 32.6°C maximum. Average hours of sunshine/day range from 3.75–9.44. The difference between the annual maximum and minimum temperature is relatively narrow. The peak temperature occurs during dry months when evapotranspiration losses are highest.

Geologically, the islands are of recent origin and the climate has produced fragile, shallow soils. The soils under virgin forest are rich in organic matter and are generally acidic, but the soils of degraded or deforested areas have lost their fertility level and water-retaining capacity. In general, the soils are medium to low in organic content and low both in available P and K (Singh et al. 1988).

Agriculture is barely 130 years old in these islands and during this period virgin forests have been cleared first for the settlement of convicts and later for refugees. Vegetables, fruits and plantation crops were introduced and cultivated. Some 17 000 ha are cropped, 12 000 ha for rice. Some islands, such as Neil, Havelock and Little Andaman, have no fallow or wasteland. The cropping pattern on different islands is dominated by rice. The area under coconut cultivation is around 29 000 ha and it is mostly in the tribal islands of the Nicobar group.

*Plant Pathology and Entomology, Central Agricultural Research Institute, Andaman and Nicobar Group of Islands, Post Box No. 181, Port Blair-744101, India.

Status of Bacterial Wilt

Bacterial wilt caused by *Pseudomonas solanacearum* is of major economic importance and occurs across the islands in almost all the vegetable-growing areas, especially of the solanaceous vegetable crops, except in Neil and Car Nicobar Islands. The disease has been recorded on a wide variety of hosts and non-hosts, and has been observed in highlands, lowlands and areas of forest cleared. The disease incidence ranges from 5–100% on tomato, 5–30% on chilli and 5–20% on eggplants. The disease has also been observed on potato and peanuts. A survey across the islands revealed that although the pathogen occurs in almost all types of soils, the soils of Neil and Car Nicobar were completely disease free (Ramesh, unpublished data).

Studies on wilt potential of soils at various inoculum levels showed a very low level of wilt incidence at a dilution of 20% of the heavily contaminated soil, survival of tomato plants being as high as 75%. At a dilution of 40% a considerable increase in the rate of wilting was recorded, and survival was reduced to as low as 15%. At a 50% dilution, survival was nil. Experiments designed to assess wilt potential of soil at different localities revealed low survival rates of tomato in soils known to be heavily contaminated as compared with soils with low levels of infestation.

Distribution

Studies on the effect of pH and salinity on survival and viability of the pathogen revealed that the pathogen can survive for 3 months at pH 6.2-6.4 and 1.65, 2.8 and 7.3 mhos/cm electrical conductivity. The pathogen was detected up to 55 cm depth in cultivated and fallow lands, with very high and almost constant abundance up to 30 cm depth, after which it declined.

Host Range

Weed plants, *Ageratum conyzoides*, *Portulaca volarasia*, *Eupatorium odoratum*, *Solanum nigrum*, *Ipomoea* sp., *Jussiaea linifolia*, *Cosmos* sp. *Amaranthus* sp., and marigold were symptomless carriers of the pathogen. The occurrence of bacterial wilt on potato, ginger, tomato, sesame, eggplant, chilli, peanut and tobacco has been observed in these islands. All the strains isolated from the plants were pathogenic to tomato and eggplants except for an isolate from a chilli plant. Ginger plants were infected and wilted only when inoculated with isolates from ginger, showing some strain specificity.

Effects of Environmental Factors on Survival

Survival of the pathogen was higher under conditions of high soil moisture. This observation correlates with field observations of higher incidence of bacterial wilt during the rainy season. It was also observed that continuous dry spells followed by rain or irrigation could immediately induce wilt under field conditions.

In the nursery, chilli and tomato seedlings had irregular lesions adjacent to their midrib on the first and second true leaves during heavy rains. Isolation of pathogen from lesions confirmed that it was *P. solanacearum*. This suggests that soil splash during the rainy season may spread the disease.

Resistance Screening

Several experiments were conducted to determine the effects of various concentrations of *P. solanacearum* on germinating tomato seeds. A higher concentration of inoculum reduced seedling vigour. However, seed germination was not affected. Further research needs to be done to standardise this methodology before comparing it to field tests. To screen germplasm, a wilt-sick plot was developed in which a highly susceptible commercial cultivar Pusa Ruby was grown continuously for two seasons. A collaborative program with the Asian Vegetable Research and Development Center (AVRDC) in Taiwan was inititated in 1983 and seeds were obtained for screening.

Continuous screening of the AVRDC material along with the released national varieties has yielded seven resistant varieties of AVRDC origin. Three have been tested under multi-locational trials and have been found suitable for cultivation. Commercial and releasecd varieties from the mainland, India Like, Punjab Chuhara, Punjab Keshari, Pusa Early Dwarf, S-12, Sel-7 Co-3, Arka Vikas, Arka Saurabh, Sel-120, and Sioux do not withstand the local strains of *P. solanaceaurm* at Garacharma, CARI complex, South Andaman. However, AVRDC lines could withstand the disease and single plant selections within segregating lines of CL-1219-0.8, Cl 949-0-12, CL-5915-402, Du-3-2-0, and EC.42 have been made over the past 7 years. Farmers prefer CL 1219-0.8 and CL 949-0-12 on the basis of fruit quality and yield.

Crop Rotation

The extensive literature on the use of crop rotations in the control of the disease is inconclusive (e.g. Graham et al. 1979; Granada and Sequeira 1983). Studies on the effect of cultivation of non-hosts on bacterial wilt incidence in infested soil with maize, cowpea and okra showed that the disease incidence was very high in okra-grown plots compared with cowpea and maize. The probable reason for the high incidence in okra plots may be interaction with root-knot nematodes which heavily infested okra.

Suppressive Soils

Low incidence of bacterial wilt occurred in rice fallow. However, in the highlands the disease incidence varied depending on the previous crop. Studies on suppressive soils of Car Nicobar and Neil Islands showed that soil factor(s) inhibited the multiplication of pathogens. Such soils when saturated with water or continuously irrigated after adding inoculum do sustain the disease. However, limited watering and irrigation did not sustain the disease even after adding the inoculum, clearly ruling out the possibility of a biological factor responsible for any suppressiveness.

Future Needs

Emphasis needs to be directed towards identifying races, host range and edaphic conditions favouring the multiplication and spread of the pathogen. Selections of AVRDC lines have provided hope for farmers in these islands and will encourage tomato production in the future.

Bacterial Wilt Potential of Soils of Andaman and Nicobar Islands

C.R. Ramesh and A.K. Bandyopadhyay*

Abstract

The Andaman and Nicobar islands (6° N and 14° N) are part of the same broad agroecological region as other Southeast Asian countries. The islands are at the fringe of monsoon tropical climate with high but uneven distribution of rainfall throughout the year. There is a conspicuous dry season from January–April when evaporation exceeds rainfall. The islands have a year-round temperature close to 30°C and a variety of soil types; circumstances suitable for observation and research on bacterial wilt of tomato caused by *Pseudomonas solanacearum*. Entisols, inceptisols and alfisols are the major soil types in production areas. Systematic surveys of the incidence of wilt in soils cultivated and uncultivated were carried out. Ferralitic soils originating from volcanic substrates (Barren and Narcondum) were highly conducive to bacterial wilt infection. Entisols, inceptisols and alfisols showed varying degrees of natural infection and were highly conducive to bacterial wilt. Mollic hapludalfs originating from the corralline parent material did not show infection in nature, even when cultivated with a highly susceptible variety of tomato (Pusa Ruby). These soils were found to be suppressive to bacterial wilt even after mixing with a sick soil in different ratios. Varying degrees of infection of tomato in different types of soils may be the result of different cropping practices followed across the islands. However, when monocropped with solanaceous crops, all soil types except mollic hapludalfs were highly susceptible to bacterial wilt.

THE Andaman and Nicobar islands of the northeastern Indian Ocean form a chain that extends for 850 km between 6°45' N. and 3°45' N. within longitudes 92°15'E. and 94°E. separating the Bay of Bengal from the Andaman Sea. The islands are the subaerail expression of the continous ridge of West Burma to the festoon of islands south and west of Sumatra. The islands are in two groups, the Andaman and Nicobar islands with a channel separating the two.

The main Andaman and Nicobar ridge runs from north to south. Topographically this ridge is very complex, falling steeply and irregularly on both sides to the floor of the Bay of Bengal and the Andaman Sea. In contrast, the islands of Riches Archipelago, Little Andaman, Car Nicobar and Chowra Islands show very low relief surrounded by coral reefs and shallow seas. Saddle peak, in the North Andaman at a height of 732 m above sea level, is the highest point in the Andaman group, while Mount Thullier, on Great Nicobar, the southernmost island in Nicobar, is 642 m high.

The soils have developed under the dominant influence of vegetation and climate over diverse parent materials. The soils can be broadly classified into three orders and seven suborders as differentiated by soil properties and pedogenic process in their development. The recognised soil taxonomic orders are entisols, inceptisols, and alfisols (Singh et al. 1988).

Bacterial wilt caused by *Pseudomonas solanacearum* is the most important factor limiting tomato production in the Andaman and Nicobar islands. The incidence of bacterial wilt is very high in some fields where reduction of yields may reach as much as 82-90% at certain times of the year (Ramesh and Ansari 1989). The disease is endemic across the islands including the forest land. It has a wide range of hosts including legumes and common weeds (Ramesh and Ansari 1989). No symptoms are expressed in some hosts. Bacterial wilt is more prevalent during the rainy

*Plant Pathology and Entomology, Central Agricultural Research Institute, Andaman and Nicobar Group of Islands, Post Box No. 181, Port Blair-744101, India.

season. Crops with a low incidence of bacterial wilt may be grown between December and May, which is the cool, dry season. Some fields, newly cleared for cultivation, often have varying levels of infestation. In some islands, such as Neil and Car Nicobar, the disease is totally absent during the growing season.

In the present study, a series of experiments was carried out to determine the wilt potential of soils collected from different locations across the islands.

Materials and Methods

Sampling of soils

The soil samples were collected at random to a depth of 40 cm. Six samples from different locations in the fields were mixed thoroughly before filling experimental pots.

To assess the wilt potential of soil samples, a procedure descibed by Felix and Ricaud (1978) was used. A constant level of moisture was maintained in the pots, ranging from field capacity to waterlogging. Thirty to forty tomato seeds, variety Pusa Ruby, a very highly susceptible cultivar, were sown in the pot for the bioassay. Wilted plants were counted daily and tested for ooze. Sterilised soil was used as a control.

Experiment 1

Soil samples were collected from tomato-growing locations on North Andaman (2 locations), Middle Andaman (2 locations), South Andaman (6 locations), Neil, Little Andaman, Car Nicobar, Narcondum and Barren Islands. Their origins were as follows: entisols of the great group, tropfluvents with pH 5.9-6.6, 0.4-1.5% organic content (OC) and 20% wilt recorded from Diglipur; inceptisols of the great group fluventic dystrochrepts with pH 5.8, O.86% OC and 40% wilt incidence from Diglipur; alfisols udalfs of the great order haplustalfs measuring pH 6.2, 1.15% OC showing 60% wilt incidence from Little Andaman; entisols of the great order troporthents, with pH 5.2 and 0.22% OC, and 5% wilt incidence (from uncultivated area from CARI, Garacharma Complex); entisols of the great order troporthents with pH 4.47 and OC 4.59% with 100% wilt in tomato (sick plot continuously under tomato cropping, from CARI, Garacharma Farm Complex); entisols of the great order troporthents with pH 5.2 and 0.22% OC with 50% wilt incidence on tomato from south Andaman, Tirur; mollic hapludalfs (coral soil) with pH 6.9–8.17 and 1.84–2.91% OC, with 0% wilt incidence on tomato from Neil Island and Car Nicobar; soils from volcanic islands of Barren and Narcondum. Barren was uninhabited; Narcondum had a small settlement and negligible area under cultivation.

Experiment 2

The Garacharma infested soil was diluted to 40%, 20%, 10%, and 5% by mixing homogenously with sterilised soil from the same location.

Experiment 3

Soils from the volcanic islands Narcondum and Barren were mixed homogeneously at 50%, 20%, and 10% with Garacharma infested soil. All the soils tested were contaminated with bacterial wilt and contained a variable and uncounted number of bacterial cells.

Results

Experiment 1

The occurrence of wilt from different localities and soil types showed that low survival of tomato plants occurred in the soils known to be heavily contaminated with the pathogen, whereas high survival occurred in soils with low levels of infestation (Fig. 1). All soils types except mollic hapludalfs were susceptible to bacterial wilt, differing only in degree.

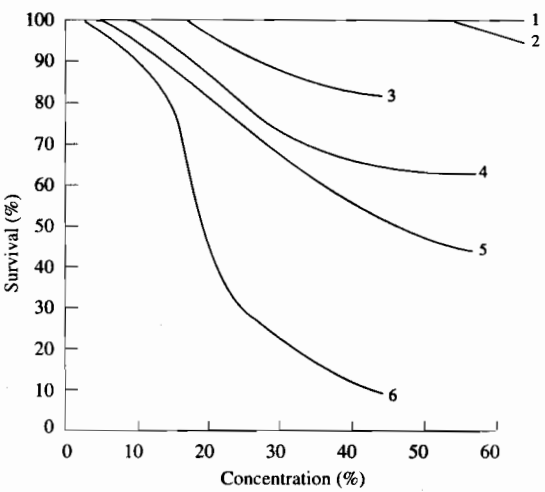

Fig. 1. Survival of tomato plants potted in different soil types. 1. Neil and Car Nicobar; 2. uncultivated soil—Garacharma; 3. Diglipur; 4. Tirur; 5. Little Andaman; and 6. sick soil—Garacharma.

Experiment 2

Very low wilt incidence was observed at dilutions of 5, 10 and even 20% of the heavily contaminated soils. Survival of tomato plants was as high as 90% at a dilution of 40% (Fig. 2).

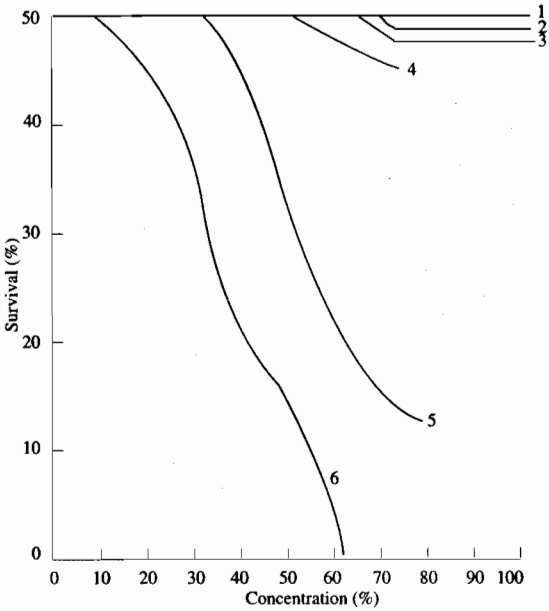

Fig. 2. Survival of tomato plants potted in varying levels of infested soil mix. Soil contamination level 1=0%; 2=5%; 3=10%; 4=20%; 5=40%; and 6=100%.

Experiment 3

Volcanic soil was free from the pathogen. However, when mixed with the inoculum, wilt occurred at 50% dilution, showing its susceptibility to the disease.

Discussion

Although biologists are conscious of the role of different soil properties in the development of, and interaction between different plant communities, little critical thought has been devoted to the effect of such soil properties on the development of microbial communities within soil habitats. Soils are an important repository for many plant pathogens and the survival of these pathogens in the absence of their specific host plants depends on a complex interplay between physical, chemical and biological factors in the soil. The situation is made more complex by the great degree of variability in the factors, both within and between soil types. Soil textural differences have been implicated in influencing survival of root nodule bacteria in some soils. Clay mineral composition, which varies between different types of soil, also influences the soil microbiology (Marshall 1975).

It is evident from the first experiment that different soil types show a varying degree of wilt potential. The wilt potential of soils also depends on the crop sequence followed, and its influence on survival of the pathogen in the soils. Soils with a lower pH and lower organic matter content supported multiplication of the pathogen. Some soils which were not cultivated had some wilt when infested and potentially may become prone to bacterial wilt if tomato or other susceptible hosts are grown in them. The bacterium was not present in any of the volcanic soils but the soils can support multiplication of the pathogen when inoculated. This also clearly shows that soil types play a major role in determining conducive factor(s) to bacterial wilt. Soils from two islands, Neil and Car Nicobar, were free from wilt, and this is where farmers grow variety Pusa Ruby. Although it may be present, only a certain threshold of inoculum could produce wilt incidence of economic importance. The absence of the disease in Neil and Car Nicobar, in spite of continuous cultivation of tomato and other solanaceous vegetables, calls for detailed studies on soil factors both biological and physical, which may play an important role in keeping the pathogen below the disease threshold.

Volcanic soils have been reported to be conducive to bacterial wilt elsewhere (Messiaen et al. 1972). Our study indicates that inadvertent introduction of the pathogen, through seeds, plant materials and soils from other islands, especially to inhabited Narcondum, could introduce the pathogen. Based on the present study, farmers are advised to plant tomato and other solanaceous vegetables according to soil types or to plan and tailor proper cropping systems dependent on types of soil across the islands.

Prevalence of Bacterial Wilt of Solanaceous Vegetables in the Mid-Hill Subhumid Zone of Himachal Pradesh, India

A.K. Sood and B.M. Singh*

Abstract

Bacterial wilt caused by *Pseudomonas solanacearum* was first observed in Kangra valley when diseased samples of brinjal (eggplant), capsicum and tomato were collected from villages Arla, Balla, and Dargeel in mid 1981. Subsequently, sporadic occurrences of this disease were recorded in other localities till 1985. The disease has since become endemic in the mid-hill, subhumid zone of Himachal Pradesh, comprising the districts of Kangra and Mandi. It also affected potato in April 1985 when 30% incidence was observed on the variety Kufri Chandermukhi in Ambada village (Nagrota block) in Kangra district.

Studies have been conducted on varietal resistance. During 1982, the reaction of 23 varieties/cultivars of tomato was recorded under natural conditions. Two varieties, V-6 and V-7 (Cuban selections), were resistant. During 1984, 29 exotic and Indian lines/varieties of tomato were transplanted in wilt-infested plots. The line EC 129156 was completely free from wilt. In another experiment, 13 recommended varieties of tomato were screened by artificial inoculation. There was 100% mortality in all varieties one month after transplanting. During 1983, the disease was most severe in spring, with 100% plant mortality in several fields. The wilt incidence in commercial varieties Yashwant (A-2), Solan Gola, Lal Mani and Solan Surkha was 57%, 19%, 18% and 23%, respectively. Further studies on varietal resistance and biological control of bacterial wilt have been initiated.

HIMACHAL Pradesh is one of the northwestern hill states of India situated 30°22'–33°12'N. and 75°45'–79° 04'E. Besides being popularly known as the 'apple State' of India, it is also well known for vegetable growing and seed production. Solanaceous vegetables cannot be grown on the plains of India because of the high temperatures. Therefore, the off-season vegetables produced in Himachel Pradesh find a ready market and sell at high prices in the plains of the adjoining States of Punjab, Haryana and Uttar Pradesh, the union territory of Chandigarh and the national capital, Delhi.

Based on elevation and climate, Himachal Pradesh can be readily divided into four distinct agroclimatic zones. While temperate areas comprised of the high hills temperate dry zone (Zone IV) with altitudes more than 2200 metres above mean sea level (masl) and the high hills temperate wet zone (Zone III) at 1800–2200 masl are suitable for the production of vegetables such as potato, peas, cauliflower, cabbage and beans, the comparatively warmer areas of mid-hill subhumid zone (Zone II) at 650–1800 masl and submontane low hills subtropical zone (Zone I) at 350–650 masl are very suitable for the production of solanaceous vegetables such as tomato, potato, brinjal (eggplant), capsicum (bell pepper and hot pepper) and cucurbits during the summer months (mid March–mid September). Several fungal, bacterial and viral diseases pose a serious threat to the successful cultivation of these cash crops.

Bacterial wilt caused by *Pseudomonas solanacearum* is an important disease of solanaceous vegetables in most Indian States (Rao et al.1975; Rao 1976). Although bacterial wilt is widespread throughout the Indian subcontinent (Sinha 1986), it is of recent origin in the mid-hill subhumid zone of Himachal Pradesh. The losses to potato crops alone have been reported to range from 30–70% (Sinha 1986), whereas in brinjal and tomato the losses are as high as 80% (Rao 1976) and 90% (Kishun 1985),

*Department of Plant Pathology, Himachal Pradesh Agricultural University, Palampur - 176 062, India.

respectively. The present paper reports on the prevalence of the disease and work done on varietal resistance in this part of the subcontinent.

Materials and Methods

Prevalence

Data on the prevalence of bacterial wilt were collected either by conducting periodic surveys during the months May–August or by keeping a record of the information obtained from the extension personnel and cultivators delivering diseased plants for diagnosis. Information recorded included on the date of collection, average wilt incidence, varieties, elevation and soil type.

Varietal screening

Screening for resistance was confined to tomato. The material consisted of locally available commercial varieties, and Indian and exotic germplasm/breeding lines received from the National Bureau of Plant Genetic Resources (NBPGR), New Delhi. During 1982–1983, screening was done under natural conditions, whereas in 1984, 1-month-old seedlings of each test variety/line were transplanted in infested plots in the Department of Vegetable Crops following standard agronomic practices. Observations on wilt incidence were recorded thrice at regular intervals.

Results and Discussion

Prevalence

Bacterial wilt in Himachal Pradesh was first observed in Kangra valley when diseased plants of tomato, brinjal and capsicum were collected and identified from villages Balla, Arla and Dargeel in mid 1981. The incidence varied from 5–30% (Table 1). The disease was very serious on tomato grown in heavy soils, especially in warmer areas. On potato, the disease was

Table 1. Prevalence of bacterial wilt in mid-hill subhumid zone of Himachal Pradesh, India.

Date	Location	Altitude (m)	Host	Incidence (%)
Kangra District				
2.5.81	Balla	930	Tomato	5–10
16.6.81	Arla	1050	Tomato, brinjal, capsicum	10
9.7.81	Dargeel	1200	Brinjal, capsicum	30
17.4.85	Ambada	1100	Potato	30
1.6.85	Bawarna	1045	Tomato, brinjal	40–50
5.6.85	Sulah	950	Capsicum	70
	Thamba	930	Tomato	100
18.5.86	Rakkar	850	Tomato, brinjal, capsicum	50
25.6.86	Kotkawara	900	Tomato	60
Mandi District				
4.8.89	Joginder Nagar	1220	Tomato, capsicum	90
	Kunnu	1150	Tomato	60
	Baragaon	1200	Tomato	50
	Harabag	1300	Tomato, capsicum	20
30.7.90	Pali	1100	Tomato, brinjal	15
	Maher	975	Tomato	25
	Panihar	800	Tomato, capsicum	70
14.8.91	Darang	1200	Tomato, capsicum	50
	Sauli Khad	850	Tomato	40
14.8.91	Chakkar	800	Tomato	30
	Bhangrotu	775	Tomato	10
Kullu Valley				
22.6.88	Ropa	1300	Tomato	10
	Panarsa	1200	Tomato	5
	Nagwain	1250	Tomato	25

first noted in April 1985 when 30% incidence was recorded on variety Kufri Chandermukhi in Ambada village (Nagrota Block). During the same period 40–50% incidence was observed on brinjal, capsicum and tomato in Bawarna area. The disease occurred sporadically in other localities till 1985 and since then has become endemic, causing up to 100% wilt in several fields in the mid-hill subhumid zone comprising districts of Kangra and Mandi (Table 1).

Although bacterial wilt is widespread in tropical, subtropical and warm temperate regions (Persley et al. 1985), in Himachal Pradesh it is endemic only in the mid-hill subhumid zone, affecting tomato, potato and capsicum. The disease is less frequent on brinjal because the Pusa Purple Cluster variety commonly grown in this zone has high degree of resistance to bacterial wilt (Sinha et al. 1989).

The disease is not endemic in Zone I of Himachal Pradesh which is contiguous with the northern plains of Punjab, Haryana and western Uttar Pradesh. In Una district, the disease does not occur, even on the highly susceptible brinjal varieties Pusa Purple Round and Pusa Purple Long which are widely grown.

Potato is the most economically important solanaceous vegetable crop grown in Himachal Pradesh. Sporadic occurrence of bacterial wilt on potato was observed in the present study. In June 1992, however, the scientist working on diseases of potato observed 30% incidence of bacterial wilt on potatoes grown at Phuladhar (Mandi) in Zone III.

Varietal screening

Twenty-three varieties of tomato maintained by the Department of Vegetable Crops at Palampur were screened under natural conditions during the summer of 1982. Only two varieties, V-6 and V-7 (Cuban selections), were found to be resistant. During 1983, disease incidences in the commercial tomato varieties Yashwant, Solan Gola, Lal Mani and Solan Surkha were 57, 19, 18 and 23%, respectively.

In a germplasm evaluation trial, 29 exotic and Indian varieties/lines of tomato received from NBPGR were screened during 1984. The data on wilt incidence are presented in Table 2. The line EC 129156 was found to be free from wilt. Other lines that performed relatively well were EC 129149, EC 126757 and EC 126761 with final incidences of 18, 38% and 43%, respectively. The first line was categorised as moderately resistant, the other two as moderately susceptible. In the other lines tested the incidence varied from 78–100% and they were rated as susceptible. Recently, Kapoor et al. (1991) reported EC 179923, EC 179924 and EC 179931 as resistant and BWR-5 as moderately resistant, and found that the incidence of wilt in lines EC 126757, EC 126761, EC 129149 and EC 129156 varied from 71–100% after artificial inoculation of seedlings followed by transplanting to infested soil. The variation in reaction of these lines from resistant to susceptible could be due either to pathotype variability (Kapoor et al. 1991) or to fluctuation in temperatures, as resistance against bacterial wilt has been shown to be temperature sensitive (Krausz and Thruston 1975; Mew and Ho 1977). Other tomato lines reported to be resistant against bacterial wilt elsewhere in India are CRA-66-Selection A (Rao et al. 1975), VC9-1UG and VC11-1UG (Bedekar 1977), 66-SS1-3 (Khan 1981), and BWR-1, BWR-5 and LE-79 (Sinha et al. 1988).

An Approach to Management of Bacterial Wilt of Potato Through Crop Rotation and Farmers' Participation

P.M. Pradhanang, R.R. Pandey, S.R. Ghimire, B.K. Dhital and A. Subedi*

Abstract

A community approach was used to manage *Pseudomonas solanacearum* bacterial wilt of potato in infested seed-production pockets of the western hills of Nepal. This included a 3-year crop rotation, clean-seed multiplication, and education of farmers on crop-hygiene practices. This paper presents a case study illustrating the success and limitations of integrated management of bacterial wilt in subsistence farming. A cropping-pattern experiment was conducted at two sites at elevations of 1750 and 2100 m above sea level. This involved a 1–3 year crop rotation and integrated management. Crops such as maize, finger millet, barley, cold-tolerant upland rice and mustard were tested. Integrated management included the application of nitrogen, and liming and weeding, to control bacterial wilt. Results of short rotations and management in controlling bacterial wilt are discussed.

POTATO is grown throughout Nepal, from the southern lowland Terai to the northern high mountains. In the lowlands it is cultivated mainly to produce market potatoes, whereas at elevations above 2000 m above sea level, potatoes are grown for both market and seed production. Because of the high quality of seed produced at high elevations, it is also the main agro-based source of income generation. Most of the demand for seed is fulfilled from the high hills because very few cold-storage facilities are available at lower altitudes.

Lumle Regional Agricultural Research Centre (LRARC) is a multidisciplinary research centre situated in the western hills of Nepal around 28°18' N. and 83°49' E. Potatoes can be grown at LRARCs in all agroecological zones stretching from the foothills (300 m) to high mountains (3000 m). Production systems vary according to altitude. Below 1000 m, potatoes are cropped after rice during the winter season, whereas from 1000–1500 m they are grown in spring on irrigated (Khet) land before the rice crop. At 2000 m and above, a single crop is grown in a year and it is a major source of food (Sthapit et al. 1987). At high altitudes, potatoes are grown in rainfed upland (Bari land) from March to August.

The climate below 1000 m is subtropical and changes with altitude to cool-temperate at 2000 m. Distribution of rainfall can be very erratic, but most precipitation occurs between May and September. At other times of the year rain is infrequent.

After late blight (*Phytophthora infestans*), bacterial wilt caused by *Pseudomonas solanacearum* is the second most important production constraint of potato in Nepal. Bacterial wilt was introduced with potato varietal development programs through the introduction and testing of uncertified planting material in wilt-free areas (Pradhanang et al. 1990). The disease has spread into many seed production areas of the eastern, central, and western regions (Shrestha 1988; Chand et al., unpublished data). Seed potato multiplication at many government farms and other research stations has been stopped due to high soil infestations (Pradhanang et al. 1987; Shrestha 1988). However, because Nepal is primarily a mountainous country, there are still numerous areas free of bacterial wilt that have potential for seed production. Nevertheless, these are under threat of contamination through transportation of infected planting material from elsewhere.

*Lumle Regional Agricultural Research Centre, PO Box 1, Pokhara, Kaski, Nepal.

Introduction of bacterial wilt has not only lowered potato production in areas of Nepal where there is already a food crop deficit, but has also reduced cash-generating opportunities from seed potatoes. Wider implications are the dissemination of disease through infected planting materials in the middle and lower hill areas, where crop diversity is high.

The objective of the study reported here was to determine whether a 2.5-year crop rotation with appropriate break crops, roguing of volunteers, and the use of wilt-free planting material could eliminate the pathogen from infested soil. The whole program is being conducted through a community approach.

In addition to the crop rotation program, a cropping-pattern experiment which involves variable durations of crop rotation and the use of different management practices to control bacterial wilt, was investigated. The traditional potato-based cropping pattern was slightly modified to develop a different cropping pattern. In terms of management practices, weed-free, negative selection, and soil amendment with urea and lime have been included. Research done elsewhere has yielded favourable results when wilt-infested soil was amended with urea and lime (Chang and Hsu 1988; Hartman and Yang 1992; Power 1983). Though the longer term prospects of the cropping pattern experiment have not been fully assessed, results from a short-term rotation are available.

Materials and Methods

A community-based crop-rotation program and cropping-pattern experiment was conducted at the villages of Sabet and Ghandruk. Sabet is a small village of some 100 households, situated at an altitude of 1700 m. The villagers' livelihood is based mainly on agriculture. Ghandruk has over 500 households, and is situated at 2000 m above sea level. The livelihood of the people is only partially based on agriculture.

The community approach

This is a joint program between the Technical Services, the Extension, and the Crop Science Sections of LRARC, with the objective of implementing and educating farmers on control measures for bacterial wilt.

Sabet and Ghandruk were selected because there was severe incidence of bacterial wilt at these villages. Education and training as to the mode of spread of disease, symptoms, the importance of crop rotation, hygienic field practices and the importance of clean planting material were provided at village meetings. At the same meetings a detailed program of crop rotation was proposed. The main issue was a 3-year prohibition of planting potatoes in infested land and roguing of potato volunteers. Farmers were asked to plant potatoes in noninfested land at both villages. Details of the crop rotation and volunteer roguing programs proposed are presented in Table 1.

Formation of Cropping System Improvement Committee (CSIC). A volunteer committee composed of respected members of the villages implemented the program. Regulations were agreed for penalising individuals who failed to abide by the crop rotation program, and the committee was assisted technically by a full-time LRARC staff member based in the village.

Options. LRARC agreed to 1. supply noninfected planting material at a subsidised rate to households if all infected potato tubers were destroyed; 2. supply transportation of subsidised fertiliser; 3. freely distribute insecticides for aphid control; and 4. provide a full-time staff member located in the village for day-to-day supervision of the program.

Rules. Villagers were: 1. prohibited from growing potato for at least 3 years in plots known to be infested; 2. required to rogue volunteer potato plants; and 3. required to plant potato crops in wilt free land.

Farmers' education. LRARC staff provided farmer training and technology transfer through mass meetings, through the Committee, or by visiting individual farmers. Monitoring was done to identify bacterial wilt in the field and in stores, and to determine the mode of transmission, the importance of roguing volunteers, the importance of clean planting material and crop rotation, and to observe the general sanitation of stores.

Table 1. Crop rotation program used during the study to control bacterial wilt of potatoes.

Site number	Period	Break crop	Remarks
1	Oct 90–March 91	Barley	Volunteer roguing in Nov. 1990
2	June–November 91	Finger millet	Volunteer roguing in June 91
3	December 91–Feb 92	Fallow	
4	April–November 92	Upland rice	Volunteer roguing in May 92
5	December 92–Feb 93	Fallow	
6	March–Sep 93	Maize	Volunteer uprooting in April 93
7	Oct–Feb 93	Fallow	
8	March–July 94	Potato	

Members of the Committee were contacted on every visit to both testing sites. Although the major objective of the meeting was to discuss the program and implementation, time was given to training or coverage of technical issues.

Tuber monitoring for the presence of vascular rot

At each store, ten tubers were checked for the presence of vascular rot, to determine the frequency of store infection, and to detect sources of infection for subsequent planting. Stores at Ghandruk were monitored in July 1990, September and December 1991, with 26, 27, and 35 stores checked. In Sabet, 38 stores were checked in December 1990.

Monitoring of volunteer potato plants

Volunteer plants germinating in former potato fields were monitored to estimate the numbers of plants germinating at different times of the year and the number of roguings required to eliminate self-sown potatoes (Table 2).

Spread of bacterial wilt through apparently healthy tubers

Potato tubers from healthy plants growing next to wilted plants were collected from Ghandruk in May 1991 and taken to the research centre for monthly examination for latent infection and vascular rot.

In February 1992, ten tubers having no visible vascular rot symptoms were planted in sterilised soil. Two tubers showing clear vascular rot symptoms were planted as a positive control. These tests were done in the glasshouse to promote rapid disease development.

Survival of *P. solanacearum* in naturally-infested soil

Soil was collected from around the roots and tubers of wilted plants at Ghandruk in May 1991. Thirty-six 500 g samples were placed in polyethylene bags. The presence of *P. solanacearum* was tested by transplanting root-pruned tomato (cv. Pusa Ruby) into each sample.

Effect of cropping pattern on bacterial wilt

Development of infested plots. This experiment was conducted at both Ghandruk and Sabet. The sites selected had relatively high bacterial-wilt infestation. All 9 m^2 plots were planted with wilt-free, but susceptible potato cv NPI/T0012. Plants were spaced at 60 cm between rows and 25 cm between plants.

The number of plants wilted in each individual plot was recorded. Plots showing low levels of wilt infestation were inoculated by planting 20 naturally- infected tubers around the rhizosphere of symptomless plants. The plots were then considered ready for conducting the cropping pattern experiment.

Monitoring of P. solanacearum *in the experimental plots.* Increase or decrease in population of *P. solanacearum* as affected by different break crops or management was monitored in each of the individual plots. The first soil sample was removed before the deliberate establishment of a sick plot. Two 500 g soil samples were collected in polyethylene bags from between 0–30 cm depth in each plot. Soil-collecting tools were disinfected between samples by washing in tap water followed by dipping in ethanol.

The second sampling was done after the establishment of infested plots. Ten 500 g samples were collected from 0–15 cm depth in each plot. Similar procedures were followed for the third sampling which was done after harvesting a mustard crop.

Soil samples placed in polythene bags were transported to Lumle Research Centre to be assayed for the presence of *P. solanacearum* using tomato plants as previously described.

Cropping pattern. Cropping patterns, which involved one to three years of crop rotation, urea and lime supplements, negative selection, and weed-free conditions, were included as management practices (Table 3). The experiment was laid out as randomised

Table 2. Monitoring methods used to determine the frequency of appearance of volunteer potato plants.

Method of monitoring	Dates of monitoring				
	1	2	3	4	5
Rational[a]	Nov 90	June 91	July 92	–	–
Frequent[b]	Nov 91	Jan 92	Feb 92	April 92	July 92
Check (farmers)[c]	–	–	–	June 92	–

[a]The main potato crop was harvested in July 1990. The first, second and third monitorings were done respectively in barley, finger millet and upland rice crops.
[b]The main potato crop was harvested in July 1991. The first four monitorings were done in a barley crop, whereas the last one was done after planting finger millet.
[c]The main potato crop was harvested in July 1991. The monitoring was done in a maize crop. The cropping pattern was potato–barley–maize.

Table 3. Treatment combinations used in the cropping pattern experiment to control bacterial wilt

Treatment	Cropping pattern	Break period between potato crops (months)
1	Potato–barley–finger millet–potato	18
2	Potato–barley–finger millet–potato (urea)[a]	18
3	Potato–mustard–potato (urea)	6
4	Potato[b]–barley–finger millet–potato	18
5	Potato–barley–finger millet–mustard–upland rice–potato	30
6	Potato–weed free–potato	18
7	Potato–barley–finger millet–potato (liming)[c]	18

[a]Urea was applied at a rate of 576 kg/ha in addition to normal fertiliser application of 40:40:20 NPK kg/ha.
[b]All wilted plants were rogued complete with tubers and the soil from around the tubers.
[c]Lime was applied at the rate of 2 t/ha.

complete blocks with three and four replications at Sabet and Ghandruk, respectively.

Only the results of the short rotation (treatment 3) are presented because this is the only treatment that has been completed.

Results

Community approach

Sabet. Because potato and other solanaceous crops were prohibited for 3 years in infested land, the Committee arranged planting of potato in an isolated grazed land at Mudhekharka (2000 m), some 30 minutes walk from the village, where potato had not been planted for some 50 years. The total area of this land was around 2.5 ha, and plots of 250 m^2 were allotted by ballot to the entire 100 households of Sabet.

Potatoes were also planted in irrigated rice land at Hile (1400 m asl) situated just below Sabet village. Here the cropping pattern had been either rice–fallow or rice–wheat. Not all farmers of Sabet own land at Hile, and so the more-wealthy farmers loaned their land to those who had none. This was a good example of community cooperation to solve a common problem.

All infected planting material from the previous season was either eaten or discarded from the village. In return, noninfested planting material was supplied. There were three varieties of potato, and farmers were impressed with cultivar NPI/T0012, because of its high yield and tolerance to late blight. Wealthier farmers cooperated in the crop rotation program, because they could grow potato in rice land during the winter season when the land would otherwise have been fallow. Poorer and landless people also participated in this program, because they were allotted land at both Mudhekharka and Hile.

Bacterial wilt was not observed at either Mudhekharka or Hile. Farmers therefore now have clean planting material, which can be used for planting in subsequent years and they will no longer require seed to be supplied from elsewhere.

Farmers were able to differentiate between the symptoms of bacterial wilt and late blight in the field. The role of the Committee was crucial in implementing strategic programs such as roguing of volunteer plants. To date, volunteer plants have been rogued twice from infested land, once in November 1990 and again in June 1991. These roguing programs were organised as campaigns to cover entire infested areas, and farmers' cooperation was thus of the upmost importance. Following the June 1991 roguing, the volunteer population was greatly reduced.

One of the reasons for farmer enthusiasm in planting potatoes at Hile was the transport of subsidised fertiliser. Without this option, it would have been impossible to deter them from growing potatoes in infested land.

Ghandruk. A sufficient quantity of wilt-free planting material was not supplied and, as a result, farmers were not asked to discard their infected planting material. The plan was to multiply 3 t of seed potato in the 1991 summer season, so that there would be sufficient planting material for distribution to all households. This was to be multiplied in an isolated field, where potato had not been grown for many years, but because the Committee did not agree with this, seed was multiplied in many different small plots. As a result, bacterial wilt was observed in one seed multiplication plot with an unknown history.

The crop rotations at Ghandruk were not implemented because farmers did not wish to sell the produce of the seed multiplication program from the 1991 summer crop. Only some 6 t of seed were collected. Therefore the program was limited to an education program to make farmers aware of bacterial wilt. The impact points given in the education program were not followed, although a majority of farmers in Ghandruk are now aware of the symptoms, the mode of disease transmission, and seed-selection techniques. Nevertheless, not only has the intensity of bacterial wilt increased at Ghandruk, but also more and more new lands are being affected by bacterial wilt (Pradhanang, unpublished data).

Six t of clean planting material were distributed in January 1992 to 162 farmers. The seed was planted in

wilt-free areas. During monitoring of these seed multiplication plots for the presence of bacterial wilt, 47 of 104 farmers had wilt in their fields. These farmers presumably planted wilt-free planting materials into infested areas.

Tuber monitoring for the presence of vascular rot

The tuber monitoring done in Sabet in July 1990 showed that 21 of 38 stores were affected by vascular rot. The tuber monitoring program at Sabet was stopped because the entire planting material from all households was discarded from the village. In Ghandruk, 18 of 26 stores were found affected by vascular rot in July 1990.

The majority of farmers used locally-produced seed as planting material (Table 4). As a result, the intensity of vascular rot was very high whenever locally-produced planting materials were used. The results of the second monitoring showed that the majority of affected tubers did not rot until December. From December until planting time (end of February or early March) temperatures are low in Ghandruk. As a result, it is highly likely that a large number of infected tubers are used as seed for subsequent plantings. A few stores were found affected by vascular rot when the seed was brought from areas other than Ghandruk.

Monitoring of volunteer plants

More volunteer plants germinated in June 1991 (41 112/ha) than in November 1990 (15 969/ha) and July 1991 (24 416/ha). A meticulous roguing program in November followed up in June, effectively reduced volunteer plants. Frequent monitoring showed that volunteers continue to grow in potato fields, although the number varies greatly between seasons (618/ha to 19 812/ha). Volunteers were found to germinate even in the cold winter temperatures of January and February, although their numbers were low. Although five roguings were made between November 1991 and July 1992, volunteer plants were not eliminated.

In the third method of monitoring, the number of volunteer plants was recorded only once in a maize crop. The cropping pattern was potato–barley–maize spread over two years. Under this system, the equivalent of 10 744 plants/ha of well grown and maintained volunteers was counted. The farmer stated that although a large number of volunteers had germinated in his maize field, he maintained the above number so that potatoes and maize did not compete strongly. Among the potato volunteers, an equivalent of 837 plants/ha was found to be infected with bacterial wilt. This result clearly indicates that volunteers were an extremely important source of disease survival. In such a situation, the best extension intervention would either be to give bacterial wilt education, or to recommend so called resistant varieties, despite their disadvantage of having latent infection.

Spread of bacterial wilt through apparently healthy tubers

In storage, vascular rot appeared after 2 months, but symptoms were not seen for another 2 months. From October onwards clear vascular rot appeared in some of the samples. However, there were no apparent external symptoms of infection. It was impossible to determine whether or not tubers were infected without cutting them open.

Though many tubers did not show vascular rot symptoms on cutting during the winter months, they subsequently showed wilting upon planting. Two of ten apparently healthy tubers harvested from healthy neighbours of wilted plants in the previous season produced bacterial wilt.

Survival of *P. solanacearum* in naturally-infested soil

That soil around the rhizosphere of wilted plants contained bacterial cells was confirmed by the wilting of the indicator plants (Table 5). However, after a lapse of 1 month following sample collection, there was no indication of the presence of wilt except in one case where one out of four plants wilted after 85 days.

Table 4. Tuber monitoring in stores at Ghandruk village.

Seed source	Sept 1991 monitoring		Dec 1991 monitoring	
	Total stores	Vascular rot	Total stores	Vascular rot
Local	21	14	19	15

Control of bacterial wilt through cropping pattern

Initial soil sampling for the presence of *P. solanacearum* indicated that the pathogen was not present in the soil samples of some replications. However, when wilt-free potatoes were planted in these plots, 10 and 33% of the plants subsequently wilted. Experimental plots were considered to be ready for evaluation of different cropping patterns to control bacterial wilt. However, soil sampling before or after the first break crop of mustard, gave no indication of high intensities of bacteria in the experimental plots.

The final wilt intensity in potato was higher than the initial wilt intensity when using mustard as a break crop. This showed that inoculum pressure was very high in the experimental plots. Wilt pathogen was not reduced by urea supplement or by mustard. The high intensity of bacterial wilt could be attributed to the short-term crop rotation.

Discussion

The main purpose of the crop rotation program is to motivate and mobilise communities to manage the shared problem of potato bacterial wilt through crop rotations and farmer education.

Mid-way through the crop rotation program, Sabet Village has had success as the entire community has adopted a crop-rotation strategy because of an increased problem of bacterial wilt in the field and severe rotting in stores. The cooperation of the farmers, an alternative site for planting potato, the availability of planting material, fertiliser and pesticide at subsidised rates, the placement of Lumle staff in the program village to supervise day-to-day management of the control program, the manageable size of the village, a sufficient extension effort and, lack of other major sources of income earning opportunity, have all helped to establish the program.

However, the community management of the disease control program has also had some negative features. Although the prohibition of planting of potato for 3 years was agreed upon, it has not been easy to maintain a complete commitment. Mid-way through the crop rotation program, one farmer wished to grow potatoes in the prohibited infested land. The reason was that the production realised from the small piece of land at Mudhekharka was not sufficient to supply the whole family. It had been made clear from the very beginning of the program, that farmers would have to sacrifice some yield of potato. In fact the farmer could easily have grown maize, millet or upland rice in the infested land. The farmer agreed that if given another plot of land (250 m^2) at Mudhekharka, potato would not be grown in the infested land. This was an impossible bargain for the Committee to agree to because if one farmer were given more land, then other farmers would have asked for the same. This was a very difficult situation because the whole program depended upon farmers' moral support. Despite requests from the rest of the community and all members of the Committee, the farmer planted potatoes in the infested piece of land. Under such a situation, it appears that such programs need legislative support to empower enforcement of regulations. Alternatively, the program should consider alternative beneficial options to be offered to the farmers to obtain enduring support and cooperation.

At the Ghandruk site, it was not possible to ask farmers to discard the entire locally-produced infected planting material. The seed potato multiplication program was also unsuccessful due to a lack of cooperation from farmers. Therefore, the program concentrated on education. However, farmers did not follow the impact points given in the training programs, and wilt incidence has continued to increase in their fields.

One of the main reasons for the difference in success between Sabet and Ghandruk Villages was village size. Grandruk is the largest village within Lumle's ECA, and so it is not unexpected that there will be dissimilarities in ideas among village leaders. Also, members of the Committee came from different wards of the village. Although most were cooperative, the committee members were afraid that if the seed production program was carried out in one ward, others might not receive sufficient planting material for the following season. As a result, the seed multiplication program did not operate smoothly (Table 6). Moreover, the farmers who were responsible for the seed multiplication program broke their promise to sell their produce to the Committee. Although the purchasing rate was modest, and was set by the farmers themselves, they did not sell the required quantity for subsequent distribution. One possible reason for

farmers' reluctance to sell planting material was that they received a higher price if they sold potatoes to the local hoteliers for market purposes.

The 6 t of planting material (Table 6) were distributed to 162 farmers. Information was given to all farmers about the need to plant noninfected seed into clean land so that they would have the required quantity of seed for the following planting season. However, the presence of bacterial wilt in 47 fields showed that farmers were not serious about following the recommendations.

Another difference between the villages was the scatter of potato-growing areas. The program was easier to implement and supervise at Sabet because potato was grown in one large block, rather than in hundreds of dispersed plots of land as in Ghandruk village. It was therefore not easy to keep potato out of infested land for 3 years. It seems that the majority of potato lands in Ghandruk are now affected by wilt due to planting of infected materials.

In addition, roguing, seed selection techniques and store hygiene practices were not follwed. Farmers did not always rogue volunteers grown in the field, but instead allowed them to grow e.g. in maize fields. Traditionally, farmers use the left over potato for subsequent planting, and the only hygiene practice followed in storage is to rogue rotten tubers which are thrown in nearby compost pits. Because Ghandruk farmers do not appear to be serious about controlling bacterial wilt, it may take time for the adoption of recommended technology. A possible reason for the lack of interest in adopting new technology against bacterial wilt was the existence of off-farm opportunities in the village.

In Nepal, cut tubers are generally used as planting materials, which may mechanically transmit the disease. The extension message should be to discard planting material if vascular rot is seen, followed by dipping the cutting knife in disinfectant. However, as this technology is not a part of the traditional potato-production system, it is highly unlikely that farmers will follow this recommendation. Under subsistence farming it is not easy to implement new technology except for varietal introduction. Training programs concerned with disease control through sanitation measures, involve women because they are responsible for much of the seed-handling business.

Survival of bacterial wilt in soil was reported to be maintained through planting infected seed potatoes, and through symptomless carrier-weeds such as *Ageratum conyzoides* and *Ranunculus scleratus* (Sunaina et al. 1989), some of which are dominant agricultural weed species in the hills of Nepal. Potato volunteers will remain the most likely source of the survival of *P. solanacearum* between potato crops. From our results of monitoring and weeding, under existing traditional systems of potato production it will be impossible to eradicate self-sown potatoes from the field. It appears that if volunteers can be rogued in November, and the following June/July, the volunteer population is greatly reduced.

At high altitudes of Nepal, there is a system of growing maize together with potato. However, quite often the large number of self-sown potatoes that grow under maize crops gives a false impression that the two crops are grown mixed. Farmers cultivate the volunteers and adjust populations of maize and volunteers. As a result they grow well together. In such a situation, it will be extremely difficult to rogue volunteers effectively. However, at Sabet, the volunteer roguing program was successful because of the farmers' cooperation and sufficient extension effort.

Latent infection of potato tubers in cooler areas and in resistant varieties has been reported by many researchers (Ciampi et al. 1980; French 1988; Nyangeri et al. 1984; Sunaina et al. 1989). At higher altitudes in Nepal, potatoes grown between March and July may wilt in June when temperatures are sufficiently high. The soil is also wet from May onwards. Plants must wilt if the seed is infected or planted in infested soil, unless the required level of inoculum is insufficient. It has been noted that the tubers from wilted plants either rot in the field or are completely rotted in stores a few weeks after harvest. Summer potatoes are harvested in July/August in the higher hills and the temperature remains warm until the end of September. As a result, there is no chance for the tubers harvested from wilted plants to remain apparently healthy until the next planting season. Therefore it is doubtful whether bacterial-wilt-susceptible varieties can withstand wilt

Table 6. Seed production program in Ghandruk.

Date	Program	Result
March–July 1991	Seed multiplication of initial supply of 3 t	Successful in many plots
October 1991	Procuring of the targeted 30 t potato	The participant farmers sold only 6 t
January 1992	Distribution of potato to the entire 500 households of Ghandruk	6 t was distributed to only 162 farmers
March–July 1992	Planting of clean material in clean fields	BW was seen in 47 seed plots out of 104 inspected plots in June 1992

when grown as summer potatoes. However, there was an indication that tubers from adjacent plants may be latently infected. This supports the need of positive selection.

Results from survival studies in naturally-infested soil using indicator plants have been erratic. The pathogen survived in soil for only 33 days, but studies elsewhere have shown that the pathogen can survive for 2 years in infested soils (Harris 1976; Shamsuddin et al. 1979). It is difficult to interpret these erratic results, but possible reasons for the variation could be low initial bacterial populations, or the death of cells due to unfavourable abiotic factors in the soil samples within the airtight plastic bag.

Susceptible tomato seedlings have been used as indicator plants to detect *P. solanacearum* in the soil (Felix and Recaud 1978; Graham et al. 1979a, b; Jenkins et al. 1967; McCarter et al. 1969). However, attempts to detect *P. solanacearum* in the soil by similar methods were not satisfactory despite the fact the fields from which soil was collected were infested. This raises a question about the reliability of tomato as the indicator plant for detection. Another possible reason for the negative results from the trial could be the sampling of soil from between 0-15 cm depth, which was dry prior to the sampling (Graham et al. 1979b). However, McCarter et al. (1969) showed the presence of the bacteria between 0-15 cm soil depth. In the trials reported here, the first and third soil samplings were made during dry months, whereas the second was in the rainy season. Though the soil samples were wet, other direct methods for detection in the soil should be tested.

The high intensity of potato wilt in the cropping pattern experiment showed that a short rotation of only 6 months was not sufficient to reduce the bacterial population. The mustard rhizosphere may have increased the pathogen population. In an experiment in the Philippines, Kloos et al. (1986) found higher potato wilt incidence when mustard was intercropped with potato. In Nepal, mustard was tested as the break crop to fit into the short crop rotation and because it is a widely grown crop.

Urea supplement did not reduce bacterial wilt. In some soil amendment experiments, application of urea has reduced the population of *P. solanacearum* (Chang and Hsu 1988; Hartman and Yang 1992). In these experiments, urea was applied together with ash which may have established a high level of antagonistic microorganisms in the experimental plots, resulting in a high intensity of bacterial wilt. Although there is no information about the effect of supplemented urea plus compost on *P. solanacearum*, it is believed that such a soil amendment may not reduce the inoculum level in soil when all the predisposing factors are in the favour of the causal organism.

The success of a community approach in programs for the management of bacterial wilt depends largely on farmer cooperation and sufficient extension support. Infected planting materials and volunteer potato plants are the main sources of inoculum in the traditional potato production systems in the hills of Nepal. It is possible to avoid contaminated planting materials, but all volunteers plants must be rogued at all times and in all plots. As regards cropping pattern, short rotation of 6 months with mustard as a break crop did not reduce the intensity of the bacteria in soil.

Acknowledgments

Lumle Regional Agricultural Research Centre is funded by ODA of British Government. We are grateful to Mr J.B. Abington, the Director of LRARC for his support of this program and for correcting this manuscript. Thanks are due to all the staffs of Technical Services Section of LRARC particularly Damodar Pokharel and Bharat Basnet who were posted at Sabet and Ghandruk respectively to implement the program. We would also like to thank Mr Lil Prasad Gurung and Yam Gurung for word processing.

Occurrence of *Pseudomonas solanacearum* in Tomato Seeds Imported into Nepal

D. D. Shakya*

Abstract

Bacterial wilt disease of tomato plants, caused by *Pseudomonas solanacearum*, occurs in warm humid parts of Nepal. Imported tomato seed is sold in Nepal without restriction. *P. solanacearum* isolated from seedlings from imported seeds was identified by pathogenicity and biochemical tests. Infected seed may be an important means of natural spread of *P. solanacearum*.

BACTERIAL wilt is a serious disease of tomato in warm temperate, subtropical and tropical parts of the world. In Nepal the disease has reduced tomato production in some districts in warm humid regions.

There has been debate in the past on the importance of seedborne infection and seed transmission of *Pseudomonas solanacearum* (Smith) Smith 1914, the bacterial wilt pathogen. The possibility of seed infection by *P. solanacearum* and its dispersal in seeds require thorough investigation to determine whether seedborne transmission is an important component of natural spread of the disease (Buddenhagen and Kelman 1964). There are reports of seed transmission of *P. solanacearum* to cotyledons and leaves of tomato and capsicum plants from contaminated seeds (Moffet et al. 1981) and the pathogen has been isolated from groundnut seed (Machmud and Middleton, 1991).

Imported tomato seed, mainly from India, is sold on the open market in Nepal. This study was undertaken to investigate whether imported tomato seed carries *P. solanacearum*.

Materials and Methods

Ten tomato seed samples used for this study were bought on the open market. The seeds had been imported from India. Twenty-five seeds from each sample in eight replicates were placed without surface sterilisation inside covered plastic dishes. The dishes were kept at room temperature (22–26°C) for two days and then incubated for 3 days at 28–30°C followed by 2–4 days at room temperature. Pieces of infected roots and stems of the resulting seedlings were macerated in a small volume of sterile distilled water in a mortar and pestle and a loopful of the macerate streaked on King's B (KB) and nutrient agar (NA) media. The plates were incubated at 28°C. Purified colonies were stored in sterile distilled water at 45°C for subsequent studies.

Pathogenicity and Biochemical Tests

Pathogenicity tests were performed on three- to four-week-old tomato seedlings (cv. Moneymaker) by injecting the stem with a bacterial suspension of approximately 10^8 cells per mL from 24-hour-old culture. The inoculated plants were kept in a humidity tent in a growth chamber maintained at 28–30°C. Suspensions were also infiltrated on tobacco leaves to test for hypersensitive reaction. Pathogenic isolates were tested by conventional methods (Lelliott and Stead 1987) to determine biochemical properties.

Results and Discussion

Seedlings from one of the 10 seed samples developed water-soaked brown discolouration on their roots within 6–9 days (Fig. 1). The percentage of diseased

*Central Department of Botany, Tribhuvan University, Kirtipur, Kathmandu, Nepal.

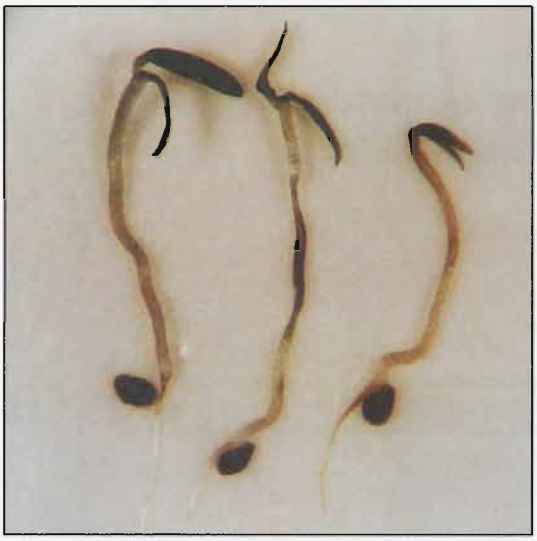

Fig. 1. Seedlings infected with *Pseudomonas solanacearum* 5 days after germinating seeds on filter paper.

seedlings with such symptoms averaged 21%. After 8–9 days infected seedlings collapsed. However, in a separate experiment, tomato seedlings germinated from the same seed and grown in pots filled with sterile soil were apparently healthy. These pots had been kept at 28–30°C without additional humidity. It is likely that these seedling were latently infected but conditions were not conducive to wilt development.

The bacterium isolated from these seedlings was non-fluorescent, and the colonies were buff white, circular, raised, smooth and glistening on KB medium. On the third day, colonies were about 1 mm in diameter. The appearance of the colonies was similar on NA medium. Symptoms were reproduced within 72 hours on tomato seedlings as a brown water-soaked discolouration extending several centimetres. Brown necrotic lesions were also produced on leaves. Two–three weeks after inoculation, adventitious roots developed along the stem as described by Fahy and Persley (1983). The bacterium was reisolated. All isolates induced a hypersensitive reaction in tobacco within 24 hours.

The isolates were positive for Kovacs' oxidase, nitrate reduction, Tween 80 hydrolysis, catalase, urease and oxidative on glucose, while negative for Gram's reagent, levan production, arginine dihydrolase, indol and H_2S production, biochemical characteristics similar to those of *P. solanacearum* (Palleroni 1984; Hayward and Watertson 1964). Acid was produced from glycerol, galactose, mannitol, sorbitol. Thus, based on physiological, biochemical and pathogenicity tests the bacterium was identified as *P. solanacearum*. Because acid was produced from both mannitol and sorbitol the isolates of *P. solanacearum* conform to neither biovar 1 nor biovar 2.

The results clearly indicate the occurrence of *P. solanacearum* in tomato seedlings grown from infected or contaminated seeds. Previous investigators had demonstrated that tomato and pepper seeds artificially inoculated with *P. solanacearum* could produce wilting plants (Moffett et al. 1981). The dispersal of wilt pathogen from localised foci in seed beds to widespread areas has also been reported (Buddenhagen and Kelman 1964). Therefore the possibility of seed infection by *P. solanacearum* and dissemination by seedborne inoculum cannot be discounted as an important means of spread in nature. Further studies are needed to clarify the dynamics of seedborne carriage and transmission of *P. solanacearum*.

Bacterial Wilt of *Perilla crispa*: New Host and New Transmission Method

W.F. Hong*, S.T. Hsu†, and K.C. Tzeng†

Abstract

Wilt of *Perilla crispa* was widespread in Kungkuan and Tunglo, Mioli county, Kuohsin, Nantou county, and Wufeng, Taichung county, Taiwan. Symptoms were first noticed after the top branches of *P. crispa* plants were clipped by a harvesting machine. The disease spread rapidly over the whole field in a pattern following the clipping direction. Stems were discoloured on the cut ends, and the lower leaves below the cut stems were epinastic. Infected plants turned brown, dried up, and died. The causal agent was identified as *Pseudomonas solanacearum*. Thirty-five strains isolated from *P. crispa* were race 1, biovar 3, and pathogenic to other solanaceous hosts and peanut. *P. solanacearum* strains from solanaceous hosts, peanut, and bird-of-paradise were not pathogenic to *P. crispa*. The pathogen was transmitted by scissors from diseased to healthy perilla plants. Stem inoculation caused 100% incidence, but disease incidence was lower after soil infestation. Symptomless plants may be an important inoculum source for the spread of the disease in the field. To our knowledge, this is the first record of bacterial wilt in *P. crispa*.

PERILLA crispa Tanaka (common name perilla), within the family Labiaceae, is an economic cash crop of importance in Taiwan for export to Japan as condiment or dye. It is also a Chinese herb and used as food in Japanese restaurants. Perilla plants are sown in spring and harvested from summer to fall. The shoot tops can be harvested 10 or more by harvesting machines during the growing period. An outbreak of a bacterial wilt of perilla was observed in the main cultivated area in recent years. In the field, the disease was first noticed after harvesting shoot tops. The objectives of the research reported here were to identify the causal agent, to investigate disease occurrence in the field, the host ranges and pathogenicity of the causal agent and to determine the mode of transmission of the new disease.

Materials and Methods

Isolation of bacteria

Strains of *P. solanacearum* were isolated from naturally-infected perilla plants growing at Kungkuan and Tunglo, Mioli county, Kuohsin, Nantou county and Wufeng, Taichung county in Taiwan during 1987–1989. The pathogen was identified on the basis of colony morphology, biochemical and physiological properties and pathogenicity tests (Fahy and Hayward 1983; Hsu and Chen 1977).

Field observation, transmission tests and pathogenicity in greenhouse

Field investigations were done in perilla production areas between summer and fall from 1988 to 1990. The wilted plants were clipped one or five times by a pair of flamed scissors and the contaminated scissors then used to clip 40 or 90 healthy plants, respectively. To measure the population from a pair of contaminated scissors, they were immersed in 10 mL of sterile water in a 50 mL beaker. A shaken, tenfold dilution of the suspension was spread on TTC medium (Kelman 1954). For the pathogenicity test, infested soil and root dipping were used. Infested soil was prepared by mixing a bacterial suspension containing 10^8 cfu/mL at a ratio of 1:10 (v/w) with dry soil before transplanting 60-day-old seedlings. Seven replications were done with 10–25 plants in each. The root-dipping method was used to ensure rapid development of the disease. Plants were pulled from the pots and roots washed with tap water before cutting the lower roots with a pair of scissors.

†Plant Pathology Department, National Chung Hsing University, No. 250 Kuo Kuang Road, 40227 Taichung, Taiwan, R. O. C.

Cross inoculation test

Plants used in pathogenicity tests were perilla, tomato, tobacco, sweet pepper, eggplant, potato, peanut and bird-of-paradise. Thirty-five *P. solanacearum* strains from perilla were cross-inoculated into these plants by toothpick-stabbing.

Results and Discussion

Observation in the field

The disease first appeared in perilla fields after clipping the top branches of perilla plants by the harvesting machine (Fig. 1), and spread rapidly along the clipping direction (Fig. 2). Disease spread was also observed following manual clipping. The first visible symptom of the disease was the development of a dark discoloration on the cut wound and epinasty of the leaves which extended downward from the darkening cut wound. The affected plant subsequently turned brown, dried up, and finally the whole plant wilted and died. There was no sign of bacterial wilt in the nursery beds or fields before harvesting. The infection rate reached 100% in some of the diseased fields. The disease recurred in the same pattern in subsequent years. Bacterial wilt on perilla caused by *P. solanacearum* is reported as a new disease in Taiwan. It has not been found in other countries. According to the local farmers' association, the disease first occurred in perilla production areas in Kungkuan and Kuasing about 8 years ago.

Identification

Based on colony morphology, physiological and biochemical properties and pathogenicity to solanaceous hosts, the causal agent of the disease was identified as *P. solanacearum*. Thirty-five *P. solanacearum* strains isolated from perilla in Kungkuan, Kuohsin and Wufeng were all race 1 and biovar 3.

Fig. 1. Harvesting machine used by farmers to clip *Perilla crispa*.

Greenhouse cross inoculation and transmission tests

Strains of *P. solanacearum* from perilla were all pathogenic to solanaceous hosts and peanut, while strains from solanaceous hosts, peanut and-bird of-paradise were not pathogenic to perilla (Table 1, Fig. 3).

The pathogen was transmitted successfully from the stem of a diseased plant to a number of healthy plants by a pair of scissors. Forty of 40 and 86 of 90 plants were diseased when they were clipped by

[b]Fifteen 2-month-old tomato plants were inoculated.

scissors that had been used to clip the tops of a diseased plants 1 and 5 times, respectively. From the five replications, a pair of scissors was found to carry 7.8×10^4–2.7×10^6 cfu of the bacterium after one clipping of a diseased stem. Stem inoculation of perilla with *P. solanacearum* produced 100% wilt, but soil infestation and root-dipping inoculation induced disease wilting of only 0–30% and 35.43%, respectively (Table 2.)

Fig. 3. *Perilla crispa* plants inoculated into leaf axils with toothpicks. Strains from *P. crispa* gave typical wilt symptoms while strains from other hosts had no effect.

Plenary Session Reports

Plenary Session

A.C. Hayward

WORK presented at this symposium has provided ample evidence of the range of variability of the bacterial wilt pathogen in genotype, phenotype and pathotype. The question should be asked to what extent the present formal and informal nomenclature successfully accommodates this range of variability and, if there is deficiency, what steps might be taken in the future to improve the situation.

There seems little doubt that at the highest level there will be further nomenclatural changes to reflect the genotypic diversity within the genus *Pseudomonas* as defined at present. It is 20 years since Palleroni et al. (1973) showed that *Pseudomonas* species were separable into 5 homology groups on the basis of DNA:rRNA homology (hybridisation); since then the phylogenetic heterogeneity of *Pseudomonas* has been confirmed by comparison of the total sequence of the 1540 nucleotides in the 16SrRNA of representative species of *Pseudomonas* (Woese et al. 1984). Representatives of rRNA group III have already been distributed into new genera; it is very likely that in the next 5 years or earlier that the species contained in rRNA group II, including *P. solanacearum*, will also be placed in new genera.

The sequence information presented at this symposium, together with the results of Palleroni et al. (1973) show that within this homology group there are two clusters of related species, one including *P. solanacearum* and *P. pickettii*, the other *P. cepacia*, *P. andropogonis* and some other species (Li et al. 1993). These two sub-homology groups are equivalent to genera established elsewhere on the basis of sequence similarity in the nucleotides of the 16SrRNA. However, it would be premature to make any taxonomic changes until additional sequence data are obtained for those species such as *P. syzygii*, the cause of Sumatra disease of cloves, the blood disease bacterium '*Pseudomonas celebense*', and some others, which show either significant levels of DNA:DNA hybridisation, reaction with probes in RFLP analysis, or similarity in phenotype to *P. solanacearum*.

The evidence from several complementary investigations has led to the belief that there may be the basis for the establishment of at least two subspecies in *P. solanacearum*. Cook et al. (1989) have shown that RFLP analysis separates all isolates of *P. solanacearum* into two major divisions, one primarily of Asian origin the other in the Americas. This suggests distant evolutionary dichotomy, an idea also supported by the data on sequence of nucleotides of the 16SrRNA in isolates of *P. solanacearum* representing biovars 1, 2, 3 and 4 (Li et al. these proceedings). However, any subspecific classification should be delayed until more detailed comparative studies have been made of larger numbers of isolates of wider geographical origin.

At the infrasubspecific level various informal systems of nomenclature have been used that are not always easy to relate to one another, and hence there has been some confusion. Differences in genotype are illustrated in the RFLP groupings of Cook et al. (1989) and in the DNA fingerprinting patterns obtained on restriction enzyme analysis (Gillings and Fahy, these proceedings). Differences in phenotype are shown in the biovar classification, and of pathogenicity and host range in races and pathotypes. It is clear that molecular methods of genotypic analysis allow far greater discrimination between strains (isolates) of *P. solanacearum* than do the phenotypic methods, and these powerful techniques find particular application in some epidemiological investigations and in plant quarantine. The traditional phenotypic methods, though simple and inexpensive to apply, often require days or weeks of incubation and the end result of the reaction may be difficult to interpret.

Biovar 2, which was previously considered to be a uniform phenotype, has now been shown to be differentiable into three sub-phenotypes (French et al., these proceedings). Two of these are metabolically less active, differ in a few phenotypic properties, and equate with race 3; they probably evolved at high elevation in the Andes as pathogens of potato and subsequently were distributed worldwide to the altitudinal and latitudinal limits of distribution of the species on latently infected planting material. The metabolically more active sub-phenotype of biovar 2 has so far been found only east of the Andes in Peru and Brazil and mainly at lower elevations. The nomenclature of these sub-phenotypes is in transition. French et al. (these proceedings) have used the term biovar 2-T for the tropical strains from Peru and Brazil, whereas others have used the term 'N-2' for the same sub-phenotype. The term biovar 2-A was given to the strains of Andean origin by French et al. (these proceedings). The latter is perhaps the best defined entity within the entire *P. solanacearum* species complex. All isolates are found in either of two closely-related RFLP groups, 26 and 27, and biovar 2-A (race 3) isolates from whatever geographical location have also been shown to be remarkably uniform in DNA fingerprinting pattern (Gillings and Fahy, these proceedings). This uniformity in genotype is matched by phenotypic homogeneity and degree of pathogenic specialisation. It seems that any future classification at the level of subspecies should recognise this major potato pathogen as a distinct and separate entity. One argument against the erection of subspecies for the two divisions of Cook et al. (1989) is that the potato pathogen would be submerged into a subspecies including pathogens specialised to other hosts such as banana. Although there is no immediate solution to this problem the objective should be an infrasubspecific classification that is universally understood and of maximum utility to plant pathologists, plant breeders and others, such as plant quarantine officers, who would make use of such a classification.

Host Resistance

E.R. French

REPORTS were presented on breeding for resistance in tomato, tobacco, groundnut, brinjal (eggplant) and pepper. The work on potato was raised in discussions. For *Eucalyptus* spp., selection for resistance has begun for another 'new encounter' disease along the Amazon river in Brazil where strains of biovars 1, 2, and 3 are devastating newly introduced species (could the biovar 2 be similar to the tropical strain described for potato: Bv 2 - T?).

Common to most hosts is the unavailability of adequate resistance, making it necessary to develop integrated control programs. The available tolerance is usually overcome by high temperatures around 30°C or more, or by high inoculum potential (present at times as systemic latent infection during screening procedures). It would seem desirable to utilise recombinant DNA procedures to transform plants with potentially superior genes; however, this has proven elusive so far in work with potatoes. The use of hybrids in breeding for tobacco resistance is noteworthy.

Tomato breeding has seen much effort over several decades with only modest or temporary gains, because of unavailability of general resistance and linkage of resistance with small fruit character. It would seem that even more collaboration is needed between scientists and institutions if significant progress is to be attained in future. It is essential to widely test germplasm to detect, and subsequently accumulate, genes for most strains of the pathogen. Marker assisted selection using molecular techniques would accelerate this process.

The genetics of heritability of resistance in all the crops mentioned is not adequately known, though types of resistance have been described for tomato (and potato) and some genomic regions described for tomato for one strain.

There was general agreement that screening for resistance must be done, or at least culminated, in the field under natural conditions; although efficient prescreening under controlled conditions can be useful.

Resistance to bacterial wilt alone is inadequate. It must be combined with resistance to other diseases and pests (especially nematodes that interact with *P. solanacearum*), and with quality and yield characteristics.

The effectiveness of integrated control of bacterial wilt of potato was shown in Nepal, where mustard was shown to be undesirable in rotation. Similarly, the integrated control of wilt of groundnut in India using a resistance component which is also sought in Uganda, showed promise.

The importance of seed transmission of *P. solanacearum* on tomato was shown in Nepal.

Molecular Basis of Virulence and Pathogenicity

Fundamental research is often difficult to fund, its eventual usefulness not always being predictable, but it is the essence of progress. Results of progress were presented on pathogenicity genes (*hrp*), polylacturonase as a component of disease, relation of exopolysaccharides to virulence and the reversibility of phenotype conversion.

Disease Management: Biological and Cultural Methods

The integrated management of tobacco wilt was presented for Australia, and for the U.S.A in the Host Resistance session.

New factors in the control of potato wilt in the warm tropics—soil amendments, antagonism by *P. cepacia*—were unveiled.

The importance of soil type in programs for integrated control in a tropical climate, as well as the colonisation of roots as a factor in biological control were covered for Guadeloupe, Taiwan and in a general review paper. Fundamental research continues to be needed in these areas. Induced resistance needs to be further explored.
